American Psychological Association

Vol. 102, No. 1 January 1974

The *Journal of Experimental Psychology* publishes original experimental investigations which are judged by the Editors to contribute substantially and significantly toward the development of psychology as an experimental science. Studies with normal human subjects are favored over studies involving abnormal or animal subjects, except when the latter are specifically oriented toward the extension of general psychological theory. Experimental psychometric studies and studies in applied experimental psychology or engineering psychology may be accepted if they have broad implications for experimental and theoretical psychology.

Manuscripts. Submit manuscripts in *duplicate* to the Editor: David A. Grant, Department of Psychology, University of Wisconsin, Psychology Building, Charter and West Johnson, Madison, Wisconsin 53706. Manuscripts must be accompanied by an abstract of 100 to 150 words *typed on a separate sheet of paper*. The abstract should conform to the style of *Psychological Abstracts*. Detailed instructions for preparation of the abstracts appear in the *APA Publication Manual*, pp. 11–12.

The Journal offers its authors the option of a "blind" review of their submitted manuscripts under the conditions described in the Special Announcement (1972, Vol. 94, No. 3, p. 325). If the author wishes to have his identity hidden from the reviewer, he should request a blind review and take sole responsibility for preparing his manuscript in such a way as to hide his identity.

Manuscripts *must* adhere to the conventions concerning reference citations, preparation of tables and figures, manuscript format, etc., as described in the 1967 revision of the *Publication Manual* of the American Psychological Association. When in doubt about practices of the Journal, authors should examine a recent issue.

Clear, concise exposition is demanded; verbose manuscripts may be returned for revision before being reviewed. Piecemeal experiment-by-experiment reporting is discouraged, and integrated series experiments executed simultaneously (e.g., most doctoral dissertations) *must* be reported in a single paper. Regular papers cannot exceed 20 printed pages. Simple experiments, replications, and supplementary experiments may be published as Short Reports of not more than three printed pages. Reports of negative results and failures to replicate published work are also acceptable if they stand on their own merits as contributions to knowledge.

Normally papers are published in order of their receipt, and the current publication lag is about ten months. All of the cost of an author's alterations in galley proof is charged to the author.

Most of the editorial decisions on manuscripts submitted to the Journal are made by the Editor or one of the Associate Editors. In addition, although listed on the Masthead as Consulting Editors, Norman H. Anderson, Helen Bohmer Daly, Murray Glanzer, and Judith Goggin serve as Special Action Editors. As such, they make the editorial decisions on a limited number of manuscripts rather than serve as reviewers for the editors.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1974: $60 domestic, $61 foreign, $6 single issue. APA member rate: $25. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive galley proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the followiug: Johnson Associates, Inc., 175 Fifth Avenue, New York, New York 10010; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. Undelivered copies resulting from address changes will not be replaced; second-class mail is not forwarded unless subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published monthly in two volumes, six issues per volume, by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and additional mailing offices.

EFFECTS OF MASKING TASKS ON DIFFERENTIAL EYELID CONDITIONING: A DISTINCTION BETWEEN KNOWLEDGE OF STIMULUS CONTINGENCIES AND ATTENTIONAL OR COGNITIVE ACTIVITIES INVOLVING THEM[1]

MICHAEL N. NELSON AND LEONARD E. ROSS[2]

University of Wisconisn—Madison

Two experiments investigated the effects of extraneous masking tasks and the viewing of a silent movie on differential eyelid conditioning. In Experiment I, involving 144 college students, masking tasks and movie viewing both significantly decreased differential conditioning performance. More masking-task than no-masking-task *S*s were classified as unaware of stimulus contingencies on the basis of a postexperimental questionnaire, and unaware *S*s showed significantly less differential responding. The masking tasks and movie also reduced the differential conditioning performance of aware *S*s, however, which suggested that factors other than awareness were important in obtaining the effects. Similar masking-task and movie effects were found in Experiment II in which *S*s were informed of the stimulus contingencies prior to the start of the conditioning. Results of the studies were interpreted as indicating that attentional or cognitive activities involving cue contingencies during the experimental session are important factors which should be differentiated from knowledge of the contingencies per se.

When *S*s in a differential classical conditioning situation are required to perform an extraneous or "masking" task during the conditioning session, their differential conditioning performance is much poorer than in the absence of such a task. This effect has been obtained in electrodermal response (EDR) conditioning studies under a variety of masking-task conditions (e.g., Baer & Fuhrer, 1970; Dawson, 1970), and in eyelid conditioning experiments (e.g., Mayer & Ross, 1969; Ross, Wilcox, & Mayer, 1967) which have used a time-estimation masking task.

Studies utilizing masking tasks with the EDR have generally done so in the context of investigating the relationship of awareness to classical conditioning performance, with the masking task being used to decrease *S*'s awareness of stimulus contingencies. Data from studies such as those cited above suggest that differential classical conditioning of the EDR is related to awareness as defined by postexperimental questionnaire reports, and under some circumstances does not occur in the absence of such awareness.

In contrast, differential eyelid conditioning studies have not directly examined the awareness–differential-conditioning rela-

[1] This research was supported by U.S. Public Health Service Research Grant HD-05653 and Training Grant 5-T01-HDOO-117 from the National Institute of Child Health and Human Development.

tionship when masking tasks are employed, although previous eyelid conditioning data suggest that awareness factors may be involved in the masking task's effect upon differential conditioning. In this regard, Spence (1966) reported that a light-guessing or probability-learning masking task slows the extinction of the conditioned eyelid response by decreasing *S*'s recognition of the acquisition–extinction transition. Similarly, Spence and Platt's (1967) failure to find a partial reinforcement decrement in acquisition under masking-task conditions was interpreted as reflecting the absence of a cognitive set assumed to be operative as a function of nonreinforcement in standard eyelid conditioning situations.

Given these single-cue conditioning effects, it appears that the reduction in differential eyelid conditioning that has been found under masking-task conditions might be a result of the masking task's effects on *S*'s awareness of the relationships among the positive conditioned stimulus (CS+), negative conditioned stimulus (CS−), and unconditioned stimulus (UCS). One purpose of the present study was to investigate this possibility by using a postexperimental questionnaire to assess *S*'s awareness of the stimulus contingencies.

While the data of eyelid conditioning studies clearly show that a time-estimation masking task reduces differential conditioning performance, there has been no attempt to determine if specific characteristics of the masking task are important in obtaining this effect. In particular, it is possible that the common response (the same time estimations) to both CS+ and CS− required by the time-estimation masking-task procedure might in itself be an important factor in reducing differential conditioning performance. To examine this possibility, the present study compared differential conditioning performance under conditions of (*a*) no masking task, (*b*) the previously used time-estimation task, and (*c*) a modified time-estimation task which required *S* to respond differently to the CS+ and CS−. Both the original and modified masking tasks required 2 time-estimation motor responses (button presses) during every intertrial interval (ITI), but the modified masking task required *S*s to spatially order their estimation responses depending upon whether the CS+ or CS− had been presented on the previous conditioning trial.

A final factor included in the study was the presence or absence of a silent motion picture for *S* to view during the conditioning. Since films have been shown in a number of previous differential eyelid conditioning studies that employed auditory stimuli, it was of interest to determine whether or not viewing a film, an act that does not involve any specific task demands, might function as a masking task in reducing S's awareness of stimulus contingencies and differential conditioning performance.

Experiment I consisted of a study and its replication. The replication was added when it appeared that too few *S*s in the original study were unaware of the stimulus contingencies to make meaningful comparisons of aware and unaware *S*s.

Experiment I

Method

Subjects. One hundred and sixty-five students enrolled in introductory psychology courses at the University of Wisconsin served as *S*s to fulfill part of a course requirement. The data from 21 *S*s were rejected, 19 because of movie projector or programming equipment failure and 2 because of *E* error. The remaining 144 *S*s, 72 males and 72 females, were randomly assigned to groups except for the restriction that each group contain an equal number of males and females. The original study and its replication each consisted of 6 groups of 12 *S*s each.

Apparatus. The experiment was conducted in a semisoundproof 3-room laboratory, with programming and recording equipment located in a control room serving 2 testing rooms. Each *S* sat in an adjustable ophthalmologist's chair facing a movie screen. To make their time-estimation responses, *S*s in masking-task groups pressed buttons located on the ends of the arms of their chairs. Monitor lights in the control room that flashed when the buttons were pressed allowed *E* to check for compliance with instructions.

Pure-tone stimuli were generated by Hewlett-Packard audio oscillators and presented through a Grason-Stadler electronic switch set for fast (≈ 10-μsec.) onset and offset ramps. The tones were delivered binaurally to each *S* through Sharpe HA-10A earphones. Movement of *S*'s right eyelid was re-

corded using standard potentiometer–polygraph apparatus.

Design and procedure. The design of each study was a $3 \times 2 \times 2 \times 2$ factorial with 3 masking-task conditions (masking task, modified masking task, and no masking task), movie vs. no movie, and the 2 counterbalanced factors of frequency of CS+ and sex of *S*. The pure-tone CSs of 800 and 2,100 Hz. were presented for 900 msec. in a continuous white-noise background. The loudness of the background white noise was matched by 4 judges to 65-db. (re .0002 dynes/cm²) free-field white noise. The loudness of the 2 tones was matched by the same judges to a 1,000-Hz. tone 85 db. above the mean threshold. The UCS was a .75-psi air puff of 100-msec. duration delivered through a 1-mm. aperture to *S*'s right cornea. An 800-msec. interstimulus interval and 15-, 20-, and 25-sec. *ITIs* ($M = 20$ sec.) were used. Equal numbers of CS+ and CS− trials were presented in a Gellermann sequence.

The original study and its replication were identical except that masking-task *S*s in the original study received a total of 110 trials with a 1-sentence recorded instruction to cease performing their task between Trials 100 and 101, while no-masking-task *S*s were interrupted with a 1-sentence statement concerning either the silent film or attention to the fixation point. Since the data from Trials 101–110 did not show systematic group differences, they were omitted from further consideration, and *S*s in the replication were given only 100 uninterrupted trials.

Instructions were given to *S*s in 2 parts. The first portion was spoken to *S* as the headset was attached and adjusted. Additional recorded instructions were delivered through *S*'s earphones after *E* had left the testing room. For the movie group, preliminary no-masking-task instructions involved telling *S* that the purpose of the experiment was to measure *S*'s reactions to "certain events" which would occur while *S* watched a silent motion picture. Both modified-masking- and masking-task *S*s were told that the experiment was concerned with time estimation during distraction, and that certain "distracting events" would occur while they were viewing a silent film. No-movie groups were treated identically except that all references to a movie were omitted. Instead of viewing a silent film, *S*s in no-movie groups were asked to fixate a 7.6-cm.-diam. flat-back disk fastened to a movie screen and illuminated by a rectangular patch of diffuse white light produced by a movie projector running without film.

The additional recorded instructions presented after *E* left the testing room began with standard neutral instructions which asked *S* to neither aid nor inhibit his natural responses. Masking-task *S*s were also instructed to judge 2- and 5-sec. time intervals from tone offset on each trial, i.e., 2 sec. after a tone had terminated *S* was to push the button on the right arm of his chair, and 5 sec. after the same tone had terminated *S* was to push the button on the left arm of his chair. Modified-masking-task *S*s were instructed to vary the order in which they pressed the buttons to estimate the 2- and 5-sec. intervals. Half of the modified-masking-task *S*s were instructed to press the right-hand button 2 sec. after the high-frequency tone terminated and to press the left-hand button 5 sec. after the high tone had terminated, but to begin with the left-hand button when performing the same two estimations after the low-frequency tone. The other half of the *S*s were instructed to report the estimations in the reverse spatial order, i.e., left then right for the estimations after the high tone, and right then left after the low tone. After questions had been answered, masking- and modified-masking-task *S*s were given the same recorded pretrial instructions given to no-masking-task *S*s, i.e., that they would now be hearing some of the tones that would occur during the experiment. Three pretrials were then given: 1 800-Hz. tone, 1 2,100-Hz. tone, and 1 unpaired air puff. Modified-masking and masking-task *S*s who initially failed to press their time-estimation buttons in the proper order were corrected by *E* between the first few conditioning trials.

Immediately after the last trial each *S* was given a postexperimental questionnaire.[2] All *S*s were asked the same 12 questions (1 question per page) which differed only slightly among the groups in order to be consistent with the appropriate task and movie condition. The first 2 questions were open ended: The first asked *S* what he thought the purpose of the experiment had been, and the second asked *S* what relationships he had noticed between the various stimuli and other aspects of the experiment. Questions 3–8 required *S* to note, on an 11-point scale, his resistance to the experimental procedures, his anxiety, annoyance, alertness, attention to the movie or the fixation point, and his irritation with the air puff. The next 3 questions asked *S* (*a*) if he noticed a change in the strength of the air puff, (*b*) if he prepared himself for the arrival of the air puff, and (*c*) to estimate the total number of air puffs and tones he had received during the experiment. The last question asked *S* to report, on an 11-point scale, the point during the experiment when he had noticed a relationship between the air puff and the tones. Masking- and modified-masking-task *S*s were given 1 extra question, inserted between Questions 7 and 8, which asked them to report how diligently they had performed their time-estimation tasks. The *S*s were not allowed to modify answers to earlier questions.

Results

A conditioned response was defined as the first pen deflection of at least 2 mm.

[2] The questionnaire used was originally developed by G. A. Kimble, and modified by J. W. Moore. The present study used most of the items reported by Moore to correlate with performance, together with some additional questions developed concerning masking-task conditions.

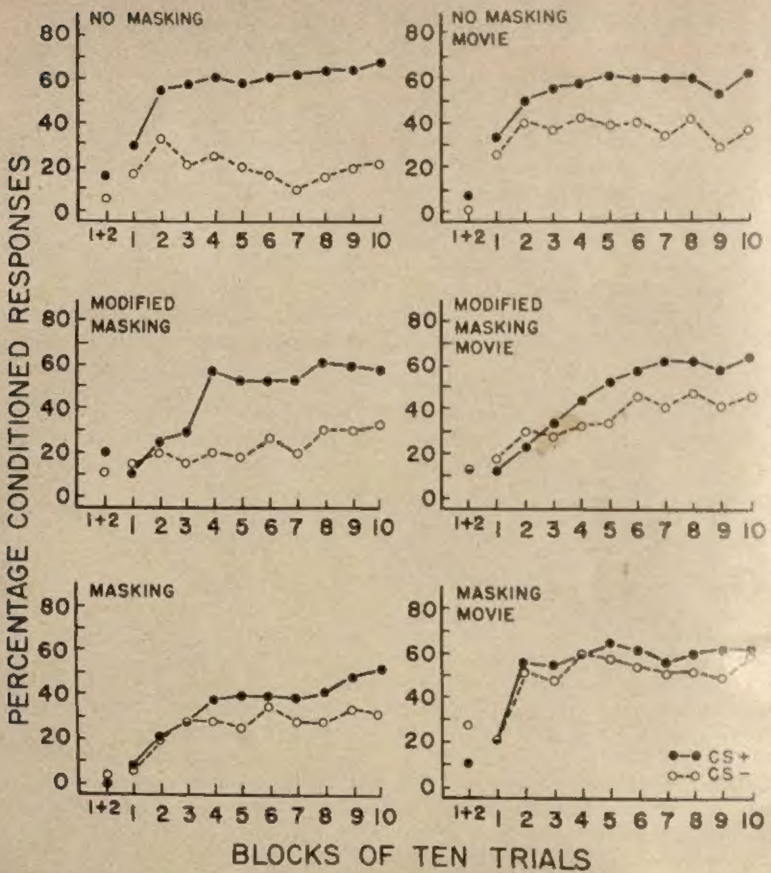

FIGURE 1. Mean percentage responses to the positive conditioned stimulus (CS+) and the negative conditioned stimulus (CS−) as a function of masking-task and movie-viewing conditions collapsed across both replications in Experiment I.

(1 mm. at the eye) in the interval beginning 200 msec. after CS onset and ending at the UCS onset.

Figure 1 presents mean differential responding to CS+ and CS− as a function of task condition and trial block for the movie and no-movie groups of both studies, with the data collapsed across the counterbalanced factors of frequency of CS+ and sex of *S*. Inspection of the figure reveals that differential responding was greatest in the no-masking-task condition, and poorest in the masking-task condition under both movie and no-movie conditions. The movie decreased differential responding under all task conditions.

A 6-factor analysis of variance was performed on difference scores for Trials 1–100, with between-*S*s factors of replications, task condition, movie condition, frequency of CS+, and sex of *S*, and within-*S*s factor of 10-trial blocks. Significant main effects of task condition, F (2, 96) = 10.81, $p < .001$, movie condition, F (1, 96) = 10.23, $p < .005$, and trial blocks, F (9, 864) = 13.61, $p < .001$, were obtained. The replication factor did not reach the .10 level, and the only significant interaction, which proved to be uninterpretable, was that of Replication × Task × Sex × Frequency, F (2, 96) = 4.07, $p < .025$.

Subsequent comparisons of the masking-task conditions revealed that the modified masking-task group was intermediate in performance, i.e., significantly superior t

the masking-task group, F (1, 96) = 4.37, $p < .05$, but inferior to the no-masking-task group, F (1, 96) = 5.39, $p < .025$. The performance of no-masking- and masking-task groups differed significantly, F (1, 96) = 19.48, $p < .001$.

Only 18 of the 144 *S*s were classified as voluntary-form responders by the Hartman and Ross (1961) derivative criterion, which was modified to prevent nonresponders from being classified as voluntary-form responders. Since the data remained virtually unchanged when the voluntary-form-responder data were omitted, separate analyses were not performed.

The postexperimental questionnaire data for the original study and replication were closely examined to determine whether the interruption between Trials 100 and 101 in the original study might have had an effect on *S*'s questionnaire responses. No effect was apparent since *S*s' mean response scores on the questions were quite similar for corresponding groups in the 2 studies. Consequently, *S*s from both studies were classified as aware or unaware of the stimulus contingencies as defined by a correct statement on the first 2 open-ended questions to the effect that the high (or low) tone was followed by a puff of air. Although it proved possible to make the classifications on a quite objective basis, all classification of *S*s as aware or unaware was performed without knowledge of the group assignment or conditioning performance of *S*.

Table 1 presents both the frequencies of *S*s classified as aware and unaware and mean differential responding over all trials for the 6 major group conditions, combined for the study and its replication. It was found that unaware *S*s were distributed unequally across the 6 groups shown in Table 1, χ^2 (2) = 8.02, $p < .02$. The table shows that (*a*) the majority of unaware *S*s were in the 2 original-masking-task groups, (*b*) the modified-masking- and no-masking-task groups did not differ in number of unaware *S*s, and (*c*) the movie had little effect on the distribution of unaware *S*s.

TABLE 1

MEAN PERCENTAGE DISCRIMINATION AS A FUNCTION OF MASKING-TASK AND MOVIE CONDITIONS FOR *S*S CLASSIFIED "AWARE" OR "UNAWARE" ON THE BASIS OF POSTEXPERIMENTAL QUESTIONNAIRE RESPONSES

Movie condition and reported awareness	Task condition		
	Original masking	Modified masking task	No masking task
Movie			
Aware	12.4(9)	11.6(18)	21.6(17)
Unaware	1.3(15)	6.7(6)	12.5(7)
No movie			
Aware	16.5(12)	26.1(17)	40.2(18)
Unaware	.9(12)	19.2(7)	31.3(6)

Note. Number of *S*s in each group is given in parentheses.

A 3 × 2 × 2 × 10 expected cell frequencies analysis of variance involving the factors of task, movie–no movie, awareness, and trial blocks was performed on the CS+/CS− difference score data shown in Table 1. A major finding of the analysis was that *S*s classified as aware of the stimulus contingencies showed significantly greater differential responding than those classified as unaware, F (1, 132) = 6.02, $p < .025$. As in previous analyses, significant main effects of task, F (2, 132) = 7.56, $p < .001$, and movie condition, F (1, 132) = 9.72, $p < .005$, were obtained. The trial blocks effect was significant, F (9, 1188) = 9.89, $p < .001$, but none of the interactions involving the trials variable reached the .10 level. Although task and movie factors did not interact with the awareness variable (both Fs < 1), planned individual comparisons were carried out on masking-task and movie–no-movie differences for aware *S*s only. The no-masking-task–masking-task difference was significant, F (1, 132) = 15.94, $p < .001$, as was the no-masking-task–modified-masking-task difference, F (1, 132) = 8.84, $p < .005$. The masking-task–modified-masking-task difference was not significant, F (1, 132) = 1.12, $p > .20$. The movie–no-movie performance of aware *S*s also differed significantly, F (1, 132) = 13.66, $p < .001$. A similar analysis carried out without the trials factor on terminal differential performance (Trials 61–100) found the same effects significant,

both in the original analysis and individual comparisons.

The data from each group in Table 1 were also examined to determine if significantly more responses were made to CS+ than to CS−. Dependent t tests of the total number of responses to the 2 stimuli revealed greater responding to the CS+ in each aware group ($p < .05$) while no unaware group showed significant differential responding. This was also true for terminal responding (Trials 61–100), except that the difference in responding to CS+ and CS− for aware *S*s tested under movie and original masking conditions only reached the .10 level of significance.

The remaining questions on the postexperimental questionnaire dealing with *S* anxiety, number of tones and air puffs received, annoyance, alertness, attention to task or movie, adaptation to USC, etc., showed nonsignificant low correlations with differential responding; no change in results was noted when the questionnaire data for aware and unaware *S*s were considered separately.

The questionnaire results did not change appreciably when a less specific definition of awareness was used, i.e., when any statement to the effect that the tones were followed by air puffs (CS+ and CS− relationships not necessarily specified) was used as the criterion of awareness.

Discussion

The data of Experiment I clearly demonstrate that performing a time-estimation task or viewing a silent film during the conditioning session results in much poorer differential conditioning performance than would otherwise be the case. Further, the degree to which differential conditioning is reduced can depend upon specific features of the masking task since differential conditioning performance with the original masking task was found to be significantly poorer than that found with the modified-masking task in the analysis involving all *S*s.

The major difference between the masking tasks was the requirement of a common posttrial response as compared to different, cue-contingent, posttrial responses. While the data might be interpreted as indicating that this response difference was responsible for the performance difference, it cannot be determined from the present study whether it was response mediation, a difference in attention to the cues, or some other factor that was the basic mechanism involved. In any case, the data do clearly demonstrate that a masking task can significantly impair differential conditioning performance even when *S* is required to attend to the CS+ and CS− in order to make different responses contingent upon which stimulus is present.

It also should be noted that the masking tasks differed in complexity and undoubtedly imposed different task demands, i.e., cognitive loads, on *S*s. However, comparing the 2 masking-task groups, poorer differential responding was found with the original masking task, which involved considerably less in the way of task demands. Since poorer differential conditioning performance was also found with movie viewing, which required no response on the part of *S*s, the data from this study do not support the position that cognitive load is inversely related to differential conditioning performance. Obviously studies which systematically vary load factors over a wide range of values will be necessary to provide definitive evidence regarding a cognitive-load–differential-conditioning relationship.

A primary purpose of the study was to determine whether the masking-task effect could be accounted for by *S*s' awareness of stimulus contingencies. Since there were more unaware *S*s in the masking-task groups, and unaware *S*s performed significantly more poorly across all conditions, it would appear that the masking task may have prevented some *S*s from becoming aware of the stimulus contingencies and thus affected their differential conditioning performance. Such an effect would be consistent with interpretations of EDR masking-task data (e.g., Dawson, 1970). However, in view of other features of the data, this factor is not sufficient in itself to account for the detrimental effects of the masking task. Most important in this respect is the fact that *S*s who clearly were aware also showed masking-task effects. Similarly, although the movie apparently did not reduce awareness (since the numbers of aware *S*s were very similar under movie and no-movie conditions), aware *S*s who did not view the movie did much better than aware *S*s who did view the movie. Thus, some factor other than *knowledge* of the relationship among the stimuli, as defined by the postexperimental reports of *S*s, would appear

to operate to reduce differential responding under masking-task and movie conditions.

It might be argued that the masking tasks and the movie simply delayed awareness until later in the conditioning session, and that the poorer differential performance of aware masking-task and movie *S*s reflected that delay. This interpretation receives some apparent support from an examination of aware *S*s' responses on the questionnaire item which asked *S* to rate the point at which a relationship between the air puff and the tone had been noticed. A 3 × 2 analysis of variance of the point of awareness data for the masking-task and movie groups did reveal that the no-masking, modified-masking-task, and masking-task group means of 89.4, 84.4, and 67.6 differed significantly, $F\ (2,\ 84) = 6.42$, $p < .005$. The pattern of individual point of awareness differences did not parallel the pattern of differential conditioning performance, however, since subsequent comparisons showed a significant difference between the 2 masking tasks, $F\ (1,\ 84) = 14.26$, $p < .001$, but no significant difference between no masking task and the modified masking task, $F\ (1,\ 84) = 1.82$, $p > .10$: the reverse was true, i.e., significant and nonsignificant differences, respectively, in the case of the conditioning performance comparisons. Further, the point of awareness means for movie and no-movie aware *S*s were quite similar, 81.8 and 83.0, respectively ($F < 1$), although a large and significant difference was found in their differential conditioning performance.

Although these data lead to the conclusion that the point of awareness data do not mirror conditioning differences in a manner that would suggest a causal relationship, it was decided to investigate further the relationship between awareness and differential conditioning in an experiment in which *S*s were informed about the stimulus contingencies *prior* to the start of the conditioning session. Presumably, if the movie and masking-task effects found with aware *S*s were due to reduced or delayed awareness of stimulus contingencies, the movie and masking task should have little effect on performance under conditions where *S* was given this information prior to the conditioning session. On the other hand, decrements similar to those found in Experiment I would support the conclusion that knowledge of stimulus contingencies is not the sole factor responsible for the masking-task and movie-viewing effects on differential conditioning.

Experiment II

Method

Subjects. Fifty-three University of Wisconsin undergraduates enrolled in introductory psychology courses served as *S*s to fulfill part of the course requirement. The data from 5 *S*s were rejected due to movie projector or programming equipment failure. The *S*s were randomly assigned to groups with the restriction that an equal number of males and females were included in each group.

Apparatus. The apparatus remained unchanged from that used in Experiment I, except for the substitution of solid-state timing equipment for Tektronix waveform and pulse generators.

Design and procedure. The design of the experiment was a 2 × 2 × 2 × 2 factorial with 2 task conditions (masking task and no masking task), movie vs. no movie, and counterbalanced factors of sex and frequency of CS+ (800 or 2,100 Hz.). The original masking task was used in this study.

The procedure replicated that of Experiment I except that each *S* was given the following additional instruction prior to the start of conditioning trials: "During the experiment you will be hearing two tones varying in pitch, or frequency. The *high* [low] tone will *always* be followed by a puff of air, while the *low* [high] tone will *never* be followed by a puff of air."

The questionnaire used in Experiment I was also given to *S*s in this experiment.

Results

Mean differential responding data as a function of masking-task and movie conditions are presented in Figure 2 with the data collapsed across the counterbalanced factors of sex and stimulus frequency. Inspection of the figure reveals that the time-estimation masking task and the movie produced fairly large decreases in differential responding relative to the no-movie–no-masking-task group.

A 5-factor analysis of variance was performed on the data of Experiment II, including between-*S*s factors of masking task, movie, sex, and stimulus frequency, and the within-*S*s factor of 10-trial blocks. Performance under the no-masking-task condition was found to be significantly superior to masking-task performance, $F\ (1,\ 32) = 8.06$, $p < .01$, and differential responding increased significantly across trial blocks, $F\ (9,\ 288) = 7.89$, $p < .001$. A significant Movie × Trial Blocks × Frequency interaction was obtained, $F\ (9,\ 288) = 2.15$, $p < .05$. It was not possible to

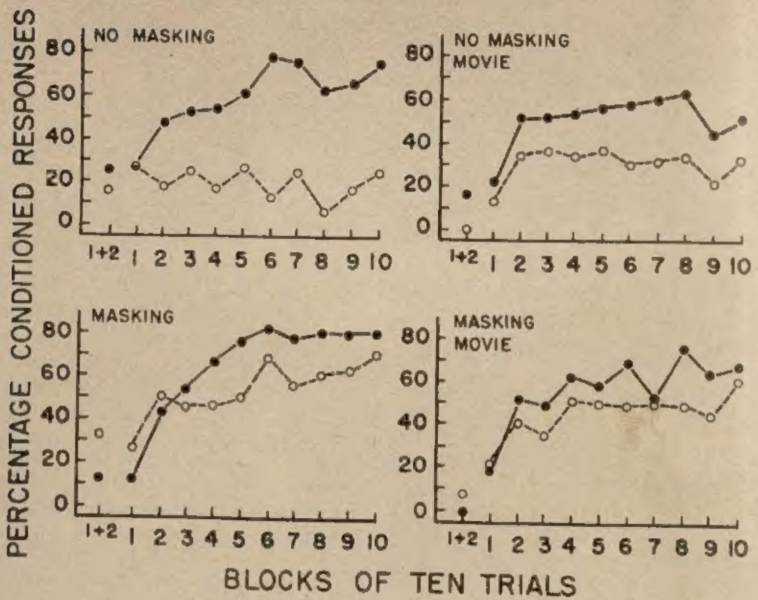

FIGURE 2. Mean percentage responses to the positive conditioned stimulus (CS+) and the negative conditioned stimulus (CS−) as a function of masking-task and movie-viewing conditions in Experiment II.

interpret this interaction in a meaningful way, and a similar interaction was not present in either replication of Experiment I.

Since it had been decided prior to the study to compare the movie–no-movie effect separately for masking and no-masking *Ss*, the analyses were carried out despite the absence of a significant Masking Task × Movie interaction. Under no-masking-task conditions, the movie effect was significant, F (1, 32) = 4.59, $p < .05$, while no effect was found under masking-task-conditions. Inspection of Figure 2 suggests that the masking task so reduced differential responding that movie effects were not possible.

Only 5 *Ss* in Experiment II were classified as voluntary-form responders, and their removal had little effect on the data. Since the questionnaire items were phrased in terms of relationships noticed during the session, *Ss*' answers would be expected to refer to their experiences during the conditioning session rather than to the information given them by *E* prior to the start of the session. The *Ss*' comments during and after the questionnaire suggested that this was the case, but confusion was expressed regarding the apparent contradiction of being informed of the contingencies and then being asked to report when they were noticed. In view of the difficulty in interpreting the questionnaire responses of informed *Ss* of this study, no further analyses of the questionnaire data are reported.

General Discussion

The results of Experiments I and II clearly indicate that the effect of an extraneous task, at least under the experimental conditions of these studies, is not due solely to a concealing or masking of the contingencies from *S* in the sense that *S* is not aware or does not have knowledge of them. It may be that the masking task prevented some *Ss* from becoming aware of the stimulus contingencies so that they could not be reported, and for that matter even without the masking task some *Ss* were not able to report the relationships. It is extremely difficult to determine if *Ss* are unaware in any absolute sense since it is not possible to be certain that *Ss* classified as unaware by one measure would be similarly classified with a different measure. In any case, *Ss* classified as aware in the present

studies performed better than those classified as unaware, and this finding, together with the fact that more masking-task *S*s were classified as unaware, suggests that *part* of the effect of the masking task was to prevent some *S*s from noticing or becoming aware of the cue contingencies so that they could later report them.

In addition, however, aware *S*s from Experiment I, as well as *S*s from Experiment II who were told the contingencies prior to the start of the study, showed reduced differential responding under masking-task and movie conditions. These data strongly suggest that a fundamental factor in differential conditioning is *S*'s attention to the stimulus contingencies, or the result of cognitive activities involving the contingencies (e.g., mediating effects of verbal expectancy), during the conditioning session.

If we assume that some attentional or cognitive activity involving stimulus contingencies enhances differential conditioning, the results of Experiments I and II follow. First, those *S*s who were unaware throughout the study, due to the demands of the masking task or for other reasons, would be less likely to attend to or engage in cognitive activity with respect to cue contingencies and therefore would be expected to perform more poorly. Masking-task or movie *S*s who became aware, or who had knowledge of the contingencies prior to the experiment, would also be less likely to attend to or become cognitively involved with the cue contingencies, but in this case because of the demands of the masking task or the distraction of viewing the movie. Thus, unaware *S*s and aware *S*s under masking-task demands or movie-viewing conditions should both show poorer differential conditioning performance.

Assuming the above to be correct, it appears necessary to distinguish between knowledge of stimulus contingencies, e.g., as measured by postexperimental questionnaires, and *S*s' attentional or cognitive activity involving the relationships among the CS+, CS−, and UCS. It is clear that *S*s may have information about the contingencies, but whether this affects differential conditioning performance undoubtedly depends upon a number of variables such as the particular demands and distracting features of the experimental situation.

Finally, it should be noted that although performance levels varied somewhat across conditions from study to study, the overall picture is one of the masking tasks and movie resulting in a high level of response to the CS−, with good acquisition curves to both CS+ and CS− in almost all groups. Ross and Ross (1972) have discussed the fact that a number of variables affect differential but not single-cue conditioning, and have suggested that single-cue conditioning involves a detection process, while differential conditioning involves detection plus recognition processes. Within this framework the major effects of the masking tasks and movie appear to be on the recognition processes necessary for good differential conditioning rather than upon detection of the CS+ and CS− per se.

SEEING THE SAME PATTERN TWICE [1]

J. ROSS, J. H. HOGBEN,[2] AND V. Di LOLLO

University of Western Australia, Nedlands, Western Australia, Aust

Two dot patterns, each either brief (3 msec.) or long (250 msec.), were di[illegible] on an oscilloscope one after the other, separated by an interval between 5 and 640 msec. The second pattern was shown in the same field as the first, or in a field which was shifted a small or a large amount to the right. Three *Ss* ju[illegible] whether the second pattern was the same as the first, or different [illegible] radically alters performance for brief patterns by modifying the validit[illegible] criminative visual cues. Performance with long patterns is altered m[illegible] by shift, since *Ss* rely on memory, not on visual effects, under almost all conditions. The results were contrasted to conclusions reached by Pollack.

Pollack (1972) carried out a large study on the detection of changes in spatial position. He made 2 observations about his findings. The first is that the "most striking result from the extended program is related to the sharp maximum in detection performance for interflash intervals (IFIs) of about 64 msec. for brief displays [1972, p. 24]." The second is that "performance is nearly at chance levels for IFIs of 250 msec., which has been taken as an estimate of the duration of the visual image [p. 24]."

At least 3 distinct time ranges are spanned within Pollack's (1972) study: (*a*) a range within which successive patterns appear to be simultaneous (Eriksen & Collins, 1967; Fraisse, 1966; Lichtenstein, 1961; McFarland, 1965); (*b*) a range within which apparent movement is observed between successive patterns or pattern components (Kahneman, 1967); and (*c*) a range beyond apparent movement, within which the first pattern is no longer visible when the second pattern appears. The purpose of the studies reported here is to examine the bases for judgments of pattern identity for dot patterns presented in the same field of view, as in Pollack's study, and for patterns presented in different fields.

If the bases for judgme[illegible] identity are discriminative cues that [illegible] in different time ranges, and if the [illegible]lative location of patterns alters the [illegible]idity of cues available in each range, [illegible]lative location of patterns should govern the effect of temporal parameters such as stimulus duration and interstimulus interval

For example, apparent movement is a valid cue for patterns presented in the same field. Where the second pattern is identical to the first, there will be no apparent movement, since the second set of dots is in registration with the first. However, where the second pattern is different, some dots appear in new positions, and apparent movement will be seen in the appropriate time range. An *O* can conclude validly that the second pattern was different if he sees apparent movement. The same is not true if the second pattern is displaced. Then none of the dots appear in old positions, and apparent movement will be seen both for identical and for different pairs. The movement cue loses its validity if patterns are displaced.

Numerosity is another cue that is valid in one case but not in another. Two identical patterns each of 8 dots seen as simultaneous will be seen as one pattern of 8 dots if the second pattern is not displaced. Two different patterns, on the other hand, will be seen as one pattern of more than 8 dots, since some of the dots in the second pattern occupy new positions. When patterns are displaced, numerosity is no longer a valid cue, since 2 patterns will be seen as one containing

16 dots, whether they are the same or different.

The appearance of 2 different patterns seen as simultaneous is illustrated, for the case of no displacement, in Figure 1. Not only are more dots seen, but there is an obvious "doubling" of some dots, those shifted to new positions to make the second pattern different from the first. This doubling is a prominent and valid cue for patterns that are not displaced. In an effort to destroy its validity, patterns were constructed to look like a pair of different patterns seen as simultaneous (see Figure 1), and were used in Experiment II.

METHOD

Experiment I

Apparatus. The visual display, consisting of 2 fields of random dots, was presented on a gridless Tektronix 602 point plotter equipped with fast P15 phosphor.

The *S* sat inside a lightproof cubicle and viewed the display through a Tektronix (Model 016-0154-00) viewing hood. The scope was positioned just outside the cubicle and the viewing hood was inserted through a light-sealed opening in the wall. The *S* viewed the display binocularly with his face resting against the viewing hood. In that position the display surface was approximately 28 cm. from *S*'s pupils. Low-level illumination of the display surface highlighted a rectangular outline at the periphery of the display area (10 × 8 cm.) and aided *S*'s focusing and convergence.

The dot fields were generated by a PDP-8/S computer, which also performed all the timing and scoring functions. The duration of all timing loops was determined with the aid of a Marconi (Model TF 2414) timer/counter under software control.

Task definition. In all conditions of the experiment the basic display consisted of the presentation of 2 fields each containing a pattern of 8 dots and separated by a variable time interval. On a random half of the trials the configuration of the dots in the second field was the same as that in the first field. On the remaining half of the trials a random 4 of the 8 dots in the second field were displaced to the *S*'s right by 2.5 mm. from the positions they held in the first field. The positioning of the dots within a field was random, subject to the constraint that no 2 dots should appear within 2.5 mm. of each other in either field. The coordinates of all dots in both fields were computed and saved in a table before each trial.

A trial was initiated by the depression of a push button hand-held by the *S*. The *S*'s task was to decide whether the configuration of dots in the 2 fields was or was not the same. He then tapped a telegraph key once or twice to indicate a *same* or *different* response, respectively. The taps were sensed and scored by the computer, which then proceeded to set up the conditions for the next trial. The setting-up procedure took less than 1 sec.

Subjects and procedure. The 3 authors, all experienced *O*s at this type of task, acted as *S*s. It might be noted that although the *O*s were not naive, they used a forced-choice design to overcome the operation of any theoretical and response biases they might have had. Each tried his best to make correct judgments.

Three variables were manipulated in this experiment: duration of the display field, location of the second field with respect to the first on the display surface, and interstimulus interval (ISI). These are considered in turn.

The duration for which a field was displayed was either brief (3 msec.) or long (250 msec.). On brief displays each of the 8 dots was plotted once only. On long displays the 8 dots were plotted sequentially and the total display was continuously refreshed for 250 msec. Brief and long field durations were never mixed within a trial: On any given trial both fields were always of the same duration.

The dots in the first field were chosen randomly on each trial from a 341 × 341 sample space matrix and were plotted on *S*'s left half of the display area within an imaginary square 27 mm. on a side (about 5° 30′ of visual angle). The first field was shown in the same location of the display area under all experimental conditions. The second field was shown in 1 of 3 locations, depending on the experimental condition. In the no-shift condition the second imaginary square was in the same location as the first (see Figure 1), in the small-shift condition it was displaced 5 mm. (see Figure 2), and in the large-shift condition it was displaced 40 mm. to the right of the first (see Figure 3).

The time interval between the 2 dot fields presented on each trial was one of the following: 5, 10, 20, 40, 80, 160, 320, or 640 msec.

The design of the experiment was thus a 2 (Field Durations) × 3 (Field Shifts) × 8 (ISI) factorial with 3 replications in each cell.

Each *S* was tested in 30 experimental sessions of approximately 10-min. duration. In any one session the levels of field duration and field shift were fixed, and 20 consecutive trials were done at each level of ISI. The sequence in which the levels of ISI were presented varied randomly for each session. Within a given session, each of the 8 subsets of 20 trials began with a warning signal (2 dots displayed vertically on the midline of the display area) followed by 4 practice trials not scored for correctness. Twenty experimental trials then followed at the same ISI as the practice trials. Within each block of 20 trials, *same* and *different* pairs occurred with equal probability. The *S*s were

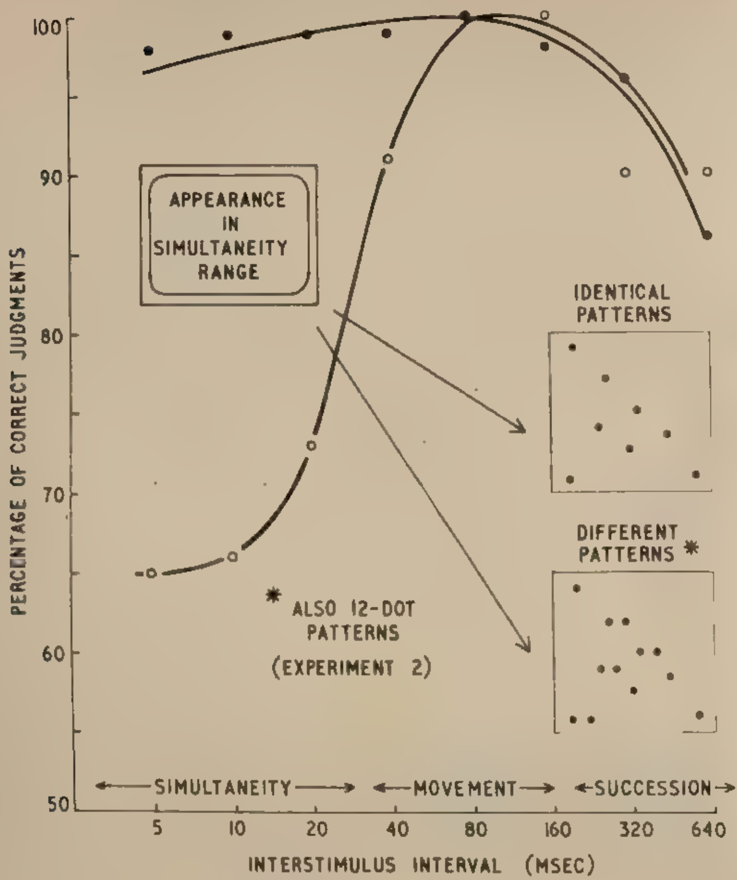

FIGURE 1. Judgment of identity and difference with patterns of brief duration (3 msec.) and no shift of field. (Filled circles show performance when all patterns contain 8 dots, Experiment I. Open circles show performance when some patterns contain 12 dots, Experiment II, and are constructed to resemble the appearance of 2 different 8-dot patterns that are seen as simultaneous. Ranges for simultaneity, apparent movement, and succession without movement are indicated, and the appearance of pairs of patterns within the range of simultaneity is illustrated.)

aware of this fact, which helped to minimize response bias.[3]

Five sessions were run at each of the 6 combinations of field duration and shift. Each *S* worked through the 30 sessions in a sequence of his own choice, making 100 judgments in each of the 48 combinations of the 3 factors.

[3] An analysis of errors for Experiment II shows that errors were predominantly (almost 5 to 1) made by calling different cases *same*, rather than same cases *different*. This may be interpreted to mean either that differences tended to be missed, or that *Ss* adopted the strategy of responding *same* more frequently, when in doubt. No detailed analysis of errors is available for Experiment I.

The *S* received no immediate feedback on the correctness of his responses. However, scores were available at the end of a session, and judgmental strategies and cues were liberally discussed among *Ss* between sessions.

Experiment II

Experiment II differed from Experiment I in 2 respects. First, all displays were presented in the no-shift condition: that is, the second field of dots was always presented within the same imaginary square as the first field. Second, each of the 8 subsets of 20 trials in a given session contained 3 types of displays presented randomly as follows: (*a*) on 25% of the trials the display consisted of

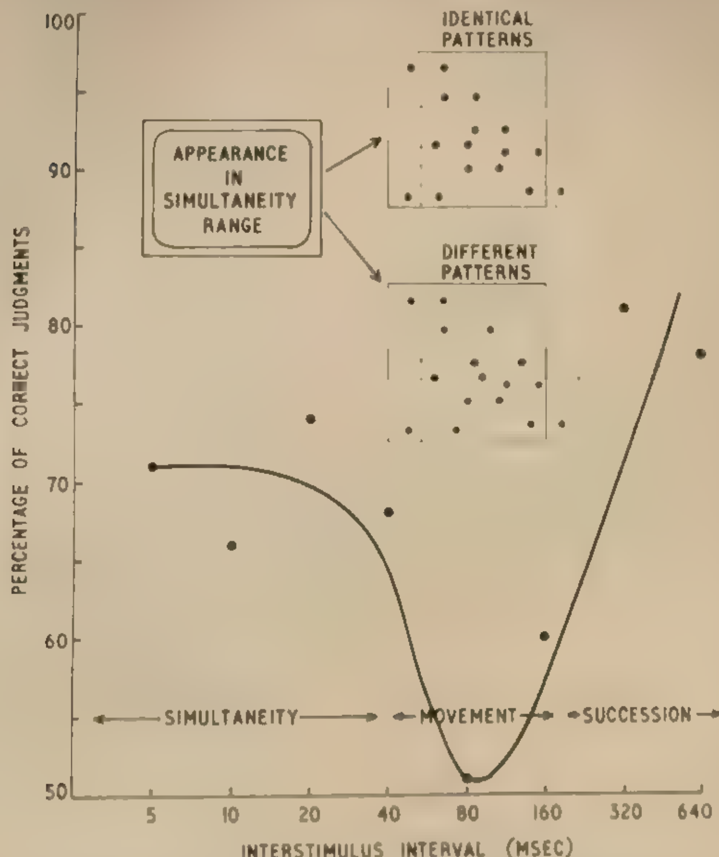

FIGURE 2. Judgment of identity and difference with brief patterns (3 msec.) and small shift (5 mm.) of field. (All patterns contain 8 dots. Experiment I. Ranges for simultaneity, apparent movement, and succession without movement are indicated, and the appearance of pairs of patterns within the range of simultaneity is illustrated.)

8 random dots, which, after the appropriate ISI, reappeared in the same positions on the screen; (*b*) on 50% of the trials a random 4 of the 8 dots were displaced 2.5 mm. to the right of their original positions; (*c*) on the remaining 25% of the trials the display consisted of 8 random dots plus another 4 dots, each of which was plotted 2.5 mm. to the right of one of the other 8 dots. The display therefore consisted of 4 pairs of dots and 4 single dots (see Figure 1). All 12 dots reappeared in the same locations after the appropriate ISI.

As in Experiment I, the *S*'s task was to decide whether the configuration of dots in the 2 fields was or was not the same.

As can be seen, Conditions *a* and *b* replicated the same conditions in Experiment I. Condition *c* was an attempt to simulate the typical appearance assumed by the total display at short ISIs in Condition *b*.

In all other respects, Experiment II was the same as Experiment I. It should be noted that, since Experiment II was run only in the no-shift condition, each *S* was tested in 10 sessions: 5 with displays of brief duration and 5 with displays of long duration.

RESULTS

Brief Patterns

Figure 1 shows the percentage of correct judgments averaged over 3 *O*s, for patterns of brief duration and no shift of field, which is the shift condition used in Pollack's (1972) study. The curve for Experiment I, in which only 8-dot patterns were used, shows high performance

at most ISI values and performance well above chance at an ISI of 640 msec. A sharp maximum in the range 80–160 msec., like that reported by Pollack, can be seen in the curve for Experiment II (Figure 1) in which some patterns contained 12 dots in an arrangement designed to cause confusion with 2 different 8-dot patterns seen as simultaneous.

Figure 2 shows results in the small-shift condition for brief patterns. Performance is at a minimum and almost chance level when ISI is 80 msec., and reaches a maximum at the 2 longest ISI values, 320 and 640 msec. Performance is at an intermediate level for ISI values in the range 5–40 msec.

Figure 3 shows results in the large-shift condition for brief patterns. Performance is at a low level for all ISIs except the longest, 640 msec., and, as in small shift, falls to a minimum, almost chance, level at an ISI of 80 msec.

Long Patterns

Results for all 3 shift conditions with stimuli of long duration are shown in Figure 4. Whereas the amount of shift makes a very marked difference in the shape of the performance curves for brief

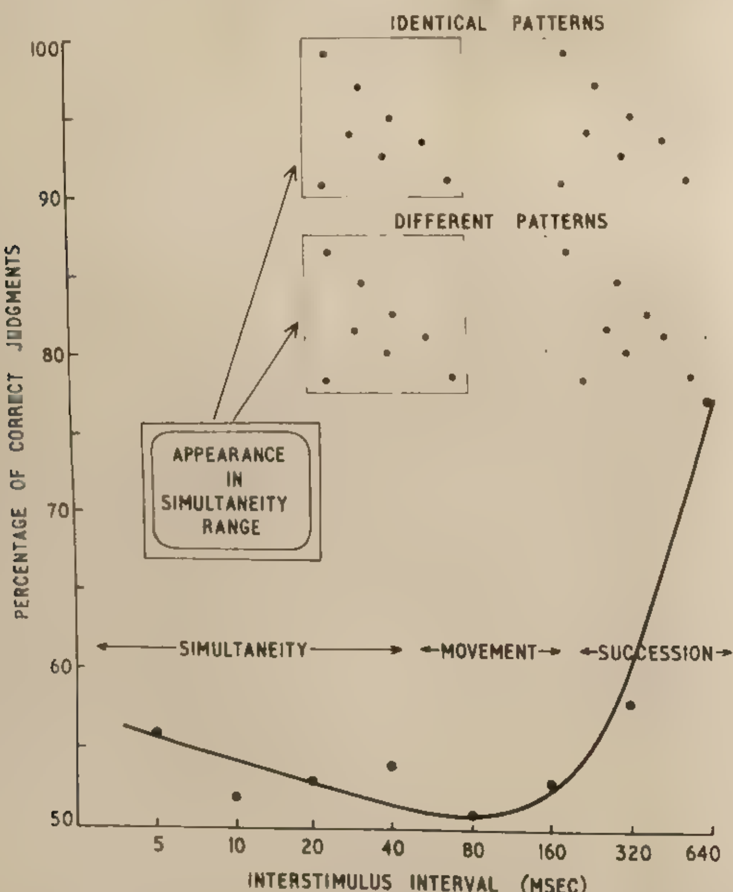

FIGURE. 3. Judgment of identity and difference with brief patterns (3 msec.) and large shift (40 mm.) of field. (All patterns contain 8 dots, Experiment I. Ranges for simultaneity, apparent movement, and succession without movement are indicated, and the appearance of pairs of patterns within the range of simultaneity is illustrated.)

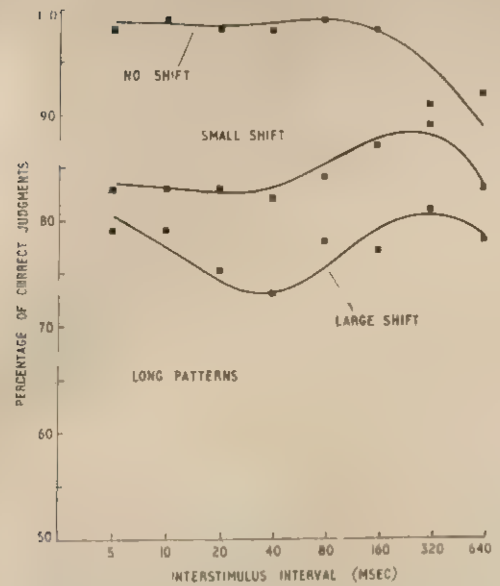

FIGURE. 4. Judgment of identity and difference with patterns of long duration (250 msec.) and no shift, small shift (5 mm.), or large shift (40 mm.) of field.

stimuli, the effect is much less for long stimuli. With increasing shift there is a progressive decline in level of performance, and some change in the shape of performance curves. For both small and large shift, performance is best when ISI is 320 msec., but still high at 640 msec.

A striking feature of the results, illustrated in Figure 5, is that any shift causes performance for brief stimuli separated by an ISI of 80 msec. to drop from near perfect to a chance level. When there is no shift, performance is virtually 100%, but when there is shift, performance is just above 50%. On the other hand, the effect of shift is much less and much the same for brief stimuli separated by the longest ISI, 640 msec., and for long stimuli separated by an ISI of either 80 or 640 msec.

DISCUSSION

Brief Patterns

Consider brief patterns first. In the no-shift case, at ISI values below 40 msec., 2 identical patterns look like 1 pattern of 8 dots, and 2 different patterns like 1 pattern of 12 dots. An *O* can tell the difference on the basis of numerosity or, even more easily, by the doubling illustrated in Figure 1. If, as in Experiment II, the validity of both cues is lowered, the task is harder in this ISI range. There is still a subtle apparent brightness cue, since some dots are plotted only once when patterns are different, but not all *O*s can use it effectively.

When ISI is within the range 40–160 msec., a sequence of different brief patterns with no shift produces apparent movement (Kahneman, 1967) and can readily be discriminated from identical patterns on this basis. At longer ISI values, apparent movement gives way to an apparent succession of patterns both for identical and different patterns, the second now being examined in terms of what is remembered of the first.

In the shift conditions, brief patterns, whether different or not, appear to be simultaneous at ISI values of 40 msec. and below. The small shift allows identical and different patterns to be distinguished on the basis of the equality of distances between pairs of

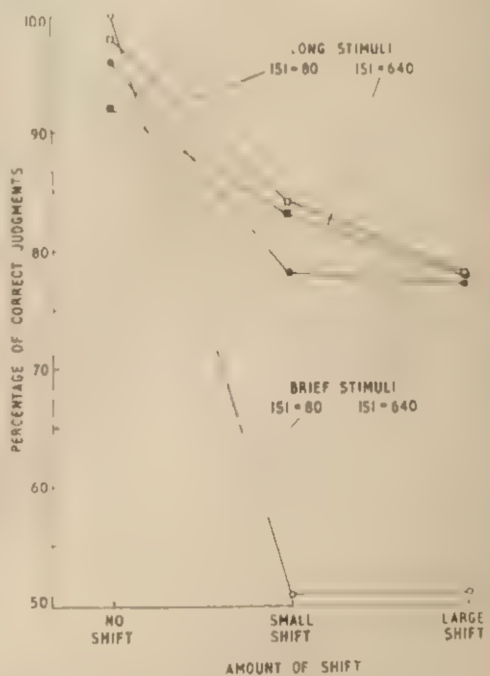

FIGURE 5. Interactions between amount of shift (no shift, 5 mm., or 40 mm.), interstimulus interval (ISI, 80 or 640 msec.), and stimulus duration (3 or 250 msec.).

points (see Figure 2). As the shift is increased to the large value, differential difference becomes more difficult to judge, and performance drops to a low level.

When ISI is between 40 and 160 msec., pronounced apparent movement is observed in both shift conditions for identical as well as different pairs of patterns. What was a discriminative cue in the no-shift condition not only fails to provide a basis for discrimination in both shift conditions, but removes the differential cues available in the lower ISI range.

At long ISI values patterns appear to come in sequence whether there is a shift or not, and performance in all conditions is based on memory, not on discriminative visual effects.

The main features of Pollack's (1972) study are captured in the performance curve for Experiment II (Figure 1) and the top curve of Figure 4. The first shows a sharp maximum in the apparent movement range; the second shows a progressive decline at long ISI values. A comparison of the Pollack-type curve for brief stimuli (Experiment II, Figure 1) with the other curves for brief stimuli (Figures 1, 2, and 3) shows that the Pollack curve is not at all typical. Its shape is explained entirely by the visual effects that are valid as discriminative cues in each of the 3 ranges of ISI values. The different shapes of the other 3 curves can also be explained in exactly the same terms.[4]

Long Patterns

Long patterns are seen as successive at all ISI values, except in the no-shift condition, where, at low ISI values, the points that are not displaced are seen as continuously present, and displaced points as intruding within an established context. Except at the low ISI range in the no-shift condition, there is no obvious visual cue and all comparisons of long patterns can be said to be based on memory. Indeed, the comparison may be based on an encoded version of the first pattern, and the slight rise in performance betwe[illegible]d 160-msec. ISI values may refle[illegible] time required for encoding.

Conclusion

The results of this study do not [illegible]ich contradict Pollack's (1972) observ[illegible] as show that they hold true only unde[illegible]cial circumstances. Performance in com[illegible]ng 2 patterns, or detecting pattern change, [illegible]aximal at ISIs of about 64 msec. and minimal above 250 msec., as Pollack observed, only if patterns are presented in the same field of view, and if the experimental design destroys the validity of numerosity as a cue for brief patterns shown at short intervals. Otherwise, as we have shown, there is no sharp maximum in the apparent movement range. When shift of field is introduced, performance may be minimal at an interval of 80 msec. and maximal at intervals as long as 640 msec.

We believe that Pollack's (1972) results, and ours, fit comfortably with the view that judgments of pattern identity and change rely on visual cues, when they are available and valid. When they are not, the task of comparison is either impossible or becomes a task of memory, comparing features of a pattern seen with what is remembered of a pattern that has been seen but is no longer visible.

[4] It should be noted that at short ISI values for brief stimuli, Pollack's (1972) *S*s would have had available the doubling cue illustrated in Figure 1. We assume that their performance remained low in this range because the experimental design made it difficult for them to discover the cue. Pollack's design is not reported in sufficient detail for us to be certain on this point.

EFFECT OF DISTANCE AND SIZE OF STANDARD OBJECT ON THE DEVELOPMENT OF SHAPE CONSTANCY [1]

DALE W. KAESS [2]

University of Aberdeen, Aberdeen, Scotland

S. DZIURAWIEC HAYNES, M. J. CRAIG, S. C. PEARSON, AND J. GREENWELL

Washington State University

The development of shape constancy as a function of the distance, size, and angle of orientation of the standard rectangle was studied. Shape constancy performance improved between 4 and 19 yr., and remained constant to 75 yr. However, a large Age × Distance interaction effect revealed that the age trend occurred with the standard rectangle at 457.20 cm., but not at 91.44 cm., regardless of the size of the object. Apparently shape constancy performance improves from "near" to "far" space as development progresses.

The perception of the physical shape of an object regardless of its orientation from the observer's fronto-parallel plane is commonly referred to as shape constancy performance. Klimpfinger (1933) found that performance on the shape constancy task improves with increasing age from 3 yr. until early adolescence, but then decreases with adults aged 31–70 yr. This apparent inverted-U development trend was replicated by Brault (1962) with data combined from different experiments. Subsequently, however, Meneghini and Leibowitz (1967) have reported a contradictory, linearly decreasing developmental trend with *S*s 4.5–19 yr. of age.

Because Klimpfinger (1933) presented the standard object at a 5-m. observational distance, Meneghini and Leibowitz (1967) supposed that the increasing portion of her obtained age trend might be an artifact of the development of perception at a "far" distance. The "distance hypothesis" suggests that the child first becomes familiar with objects within his reach and only gradually is able to perceive objects at a distance (Piaget, 1967; Vernon, 1962). Wohlwill (1963) has reviewed studies which show that size constancy, or the perception of the size of an object regardless of its distance, is reduced with increased observational distance, and the effect of distance is apparently greater with younger *S*s than with adults. However, there are few data available concerning the parameter of observational distance in shape constancy development.

The only study of the development of shape constancy in which observational distance was systematically varied was reported by Meneghini and Leibowitz (1967). Children 4.5–19 yr. old were shown a rotated 3-cm.-diam. disk at either 91.44- or 457.20-cm. distances, and required to compare it with the comparison series objects presented at a 91.44-cm. distance. Shape constancy performance apparently decreased with age with the test object at a 91.44-cm. distance, but was poor at all ages with the test object at the 457.20-cm. distance. The data were interpreted to demonstrate the validity of the distance hypothesis. However, it is possible that the poor performance by all age groups at the 457.20-cm. distance represents chance performance resulting from the use of too small an object at that distance. The 3-cm. disk shown at 457.20 cm. subtended a visual angle of less than 1°. Thus, the

[1] The authors wish to thank Emma Lou Kenzy, Betty Scott, and Sherril Richardz for making the nursery school subjects available; Patrick Mooney, Principal, and the staff of Edison Elementary School, Pullman, Washington, for providing space for testing 11-year-olds; and staff and members of the Pullman Senior Citizens Center for providing space and data. Also, the assistance of Connie Kaess at every stage of this project is gratefully appreciated.

[2] Requests for reprints should be sent to Dale W. Kaess, Department of Psychology, King's College, University of Aberdeen, Old Aberdeen AB9 2UB, Scotland.

task was probably difficult for the *S*s to perform (Gibson, 1969, p. 365).

Furthermore, since the visual angle subtended by the standard object varied directly with the observational distance, projective size and distance were completely confounded in the Meneghini and Leibowitz (1967) study. That is, the projective size of the standard object was always 5 times larger at the 91.44-cm. distance than it was at the 457.20-cm. distance. Consequently, their results could be interpreted in terms of either observational distance and the distance hypothesis, or in terms of the projective size of the test object as determined by the visual angle subtended by it. This latter interpretation in terms of the size of the test object involves the assumption that acuity for the cues necessary to shape constancy performance varies with the projective size of the object being judged.

Consequently, the present study is designed to investigate the influence of observational distance upon the development of shape constancy performance. Standard objects of 2 sizes have been presented, so that the visual angle subtended by the objects at the 2 distances was systematically varied. Furthermore, elderly *S*s were also used in an attempt to replicate the decreasing trend with older adults, as obtained by Klimpfinger (1933).

Method

Subjects. There were 96 *S*s comprising 4 age groups averaging 4.3, 11.4, 19.5, and 75.6 yr. Each of the 24 *S*s of each age group was randomly assigned to one of 2 treatment combinations denoted by the distance from which the standard object was viewed, so that there were 6 males and 6 females in each group. All *S*s reported having normal binocular vision, at least with corrective lenses.

Apparatus. The standard objects were presented 15 cm. inside a 122 × 91 × 30 cm. flat-black viewing box with a 30-cm.-sq. aperture in the front. The background, 15 cm. behind the object, was also flat black in color. This apparatus was placed on the front edge of a table at *S*'s eye level so that the standard object was either 457.20 or 91.44 cm. from *S*. Comparison objects were presented individually on the background of a similar 122 × 91 × 15 cm. box placed at eye level 91.44 cm. to *S*'s right or left. The *S*s viewed the objects binocularly. The tops of the viewing boxes were open, so that illumination was provided by overhead room lights. There were no visible shadows present on either stimulus.

Stimuli. Two rectangular standard objects were used. They were cut from white textured poster board and mounted upon 2-mm. wires along their longer, vertical dimensions. The standard objects were 7.62 × 8.89 cm. and 38.10 × 44.45 cm., thus preserving the same horizontal-to-vertical ratio. The sizes were chosen so that the larger object would present the same projective size at 457.20 cm. that the smaller object presented at the 91.44-cm. distance. Each of these standard objects was rotated about its vertical axis to either 25° or 75° from the fronto-parallel plane for presentation.

The comparison objects were 2 separate sets of 17 rectangles each with the same height as the corresponding standard object (8.89 or 44.45 cm.), and varying in steps of .63 cm. from 5.04 cm. narrower to 5.04 cm. wider than the corresponding standard object. These comparison objects were also cut from white textured poster board.

Procedure. On an individual trial, one of the 2 standard objects was presented at either a 25° or a 75° orientation with either a 91.44- or a 457.20-cm. observational distance. The rectangles of the comparison series were shown individually in random order 91.44 cm. to *S*'s right or left. The large or small comparison series forms were always presented with the rectangle of the same height. A different random order was used with each trial for each *S*, and order of presentation of trials was counterbalanced across *S*s in each Age × Distance group.

Instructions. All *S*s were given instructions similar to those used by Kaess (1970). It was explained that *S* was participating in a test of how well he could tell the "real" shape of an object even when it is turned to the side. The *S* was shown (by measuring the physical shape of a rotated rectangle) that the real shape remains the same regardless of the orientation. However, no mention was made of the apparently narrower projective shape, or that *S* should compensate for the effects of angle. The youngest *S*s were also told that they were "playing a game," and that they should attempt to be correct every time. No feedback was given during testing, however.

Results

The basic data were the median widths of those comparison series rectangles judged to be equal to each standard rectangle in each series of trials by each *S*. These values were converted to constant error scores by subtracting the width of the standard rectangle from that of the median comparison rectangle judged equal to it, so that the data for the 7.62- and 38.10-cm. rectangles would be comparable (Table 1). The constant errors were subjected to a 4 (age) × 2 (sex) × 2 (distance) × 2 (size)

× 2 (angle) analysis of variance, with age, sex, and distance as between-*S*s effects.

The main effect of age, F (3, 80) = 3.48, p < .025, was significantly large. Comparisons of individual means (Neuman-Keuls technique) indicate that the 4-year-olds' mean constant error was significantly larger than that of the 11-year-olds, which was in turn larger than the means of both the 19- and 75-year-olds. Apparently, shape constancy performance improves between 4 and 19 yr. of age, and remains relatively constant with older *S*s.

The effects of distance, F (1, 80) = 13.46, p < .001, and of angle, F (1, 80) = 4.33, p < .05, were also significantly large. The *S*'s judgments of the widths of the rotated forms were more accurate when the forms were viewed from a near, 91.44-cm., distance or when the forms were viewed at 25°, rather than 75°, rotation from their fronto-parallel plane. The Sex × Distance interaction, F (1, 80) = 4.37, p < .05, was also significantly large, however. Comparison of individual means reveals that while the effect of distance obtained with *S*s of both sex, the effect was more pronounced with the male *S*s.

As can be seen in Figure 1, the Age × Distance interaction, F (3, 80) = 4.21, p < .01, was large. Comparisons of individual means reveal that there were no significant differences between age groups with the standard object at the 91.44-cm. distance. But with the standard object at the 457.20-cm. distance, the 4-year-olds' mean constant error was significantly larger than that of the 11-year-olds, which was in turn larger than all others. The mean constant errors of the 19- or 75-year-olds with the 2 observational distances did not differ significantly. Thus, the influence of the distance of the standard object is reduced as age increases, and does not produce a significant difference in the shape constancy performance of 19- and 75-year-olds.

Finally, the Age × Size interaction, F (3, 80) = 2.83, p < .05, was also significantly large. This effect was apparently produced by a curvilinear developmental trend with the 38.10-cm. test object, but a linear trend with the 7.62-cm. object. In particular, the 19-year-olds overestimated the width of the 38.10-cm.-wide form, but all other group means for the Age × Size factor represented underestimates. Thus, this interaction apparently resulted from an anomalously high mean by the 19-year-olds with the large standard object.

Neither the main effect of size nor any additional interactions involving size or Age × Distance were significantly large in

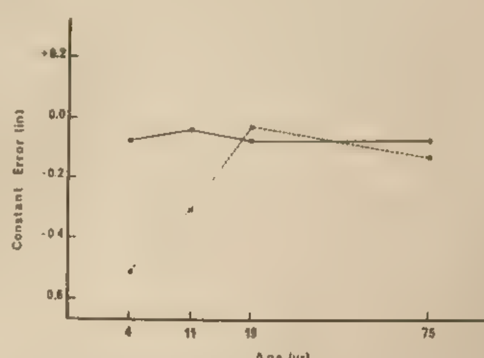

FIGURE 1. Mean constant errors (point of subjective equality minus standard) of judgments of the physical widths by *S*s who viewed the forms from 91.44-cm. (solid line) and 457.20-cm. (dashed line) distances. (Mean constant errors are averaged over sizes and angles of rotation.)

the analysis of these data. Apparently, the effect of presenting 7.62- or 38.10-cm.-wide standard objects at the 2 distances so that the same projective size is maintained does not decrease the effect of distance upon the development of shape constancy performance.

Discussion

The results of the present study show that shape constancy performance improves with age, at least between 4 and 19 yr. of age and with objects at a 457.20-cm. distance. The present results thus contradict those of Meneghini and Leibowitz (1967). As suggested by Gibson (1969, p. 365), it seems probable that the decreasing age trend found by Meneghini and Leibowitz resulted from the type of instructions used in their study. Their instructions can probably be termed "apparent" (Landauer, 1969). Such instructions have been shown to result in lower degrees of constancy performance and decreasing developmental trends (Kaess, 1970). When care is taken to insure *S*s' understanding of the task, shape constancy performance improves with age (Kaess, 1970, 1971). Klimpfinger's (1933) data also reveal an increasing developmental trend with children. However, the older groups of her study showed an apparent decrease of shape constancy performance, while the older groups of the present study do not. This discrepancy may also have resulted from differences in instructions, since Klimpfinger required projective shape judgments while the present study involved physical shape judgments. Apparently, when the perceptual task involves judgments of the physical shape of the object, shape constancy performance improves with age until adulthood and does not decrease with older *S*s.

Superimposed upon this developmental trend are the effects of other factors which affect the level of shape constancy performance. Shape constancy performance is more accurate when the object is nearly facing *S*, and when the object is at a 91.44-cm. distance. The reduction of shape constancy performance as a result of increased distance does not seem to be a product of the reduced visual angle subtended by the distant object, as expected, since there was no significant Age × Distance × Size interaction. Apparently, the "distance effect" is obtained with both large and small rectangles and is not entirely produced by differences in the visual angles of the standard and comparison forms.

It is possible that the distance effect results from the particular comparison technique of the method of limits paradigm used here. The present study involved variation of the distance of only the standard object. The comparison series was always presented at the near distance. Thus, the *S*s were required to match the standard stimulus to the comparison series forms when the distances of the forms were equal (near distance) and when the distances were disparate (far distance). A further test of the distance hypothesis in which the distance of the comparison series is varied simultaneously with that of the standard object would be of interest. In this manner it might be possible to determine whether the observational distance effect results from judgments of the standard form per se, or from changes in the ability to judge 2 forms, each of which is at a different distance.

Regardless of the locus of the effect, however, the significant Age × Distance interaction obtained in the present study suggests that the effect of observational distance depends upon the age of the *S*s. The results of the present study thus support the hypothesis of Vernon (1962) and Piaget (1967) that perceptual development proceeds from near to far space as age increases. At least with these experimental techniques, the effect of increased distance of the standard form is apparently greater with younger than with older *S*s. Consequently, developmental trends of shape constancy performance are similar to those for size constancy performance. Each task involves judgments of an "object-at-a-distance" (Gibson, 1969, p. 366), and developmental trends of performance on each task depend upon the observational distance involved.

ACQUISITION AND RETENTION OF MNEMONIC INFORMATION IN LONG-TERM MEMORY[1]

PAUL M. WORTMAN[2]
Northwestern University

PHILLIP B. SPARLING
Duke University

Paivio's (1969) 2-process theory of associative learning postulating differential effects on recall for word abstractness concreteness, and imaginal and verbal mediators, was evaluated within the context of mnemonic encoding. The mnemonic learning was self-paced, involving multiple lists with an immediate and delayed test of retention after 1 wk. The results supported a prediction of a trade-off in differential acquisition time for nondifferential recall performance in situations where presentation rate was not strictly controlled. A large amount of forgetting was found, independent of word or mediator type, thus supporting the notion that acquisition and retention are separate mechanisms. Finally, a highly significant effect for word type was found despite the relaxation in presentation rate, and its implication for modification of the theory was discussed.

The recent revival of interest in mnemonic techniques has led to a new theory of paired-associate (PA) learning (Bower, 1972; Paivio, 1969). According to this formulation, PA learning consists of 2 processes or mediational sets involving the formation of either verbal or imaginal associations. These processes interact differentially with 2 types of to-be-learned information—abstract and concrete words. Thus, image processes are supposed to be more predominant in learning concrete words than abstract words, since concrete nouns have readily available imaginal components of meaning, whereas abstract nouns do not. Verbal mediators, on the other hand, are assumed to be unaffected by changes in word type. While this predicted interaction has proved somewhat difficult to obtain, it has received empirical confirmation (Paivio & Foth, 1970).

The rather "elusive" nature of this phenomenon, however, raises a number of questions. On methodological grounds, how dependent is the interaction of word or item type and mediational set on the rather long study intervals used by Paivio and Foth (1970)? And, in particular, what happens when these intervals are made even longer? On the theoretical side, what is the relative importance of these interacting variables? And do they affect the retention of information in long-term memory (LTM)? The results reported by Paivio and Foth indicate a consistent superiority in learning of concrete over abstract PAs that is independent of encoding process, while the differential effects of these associative strategies seem highly dependent on temporal and instructional variables.

The present study seeks to assess this 2-process theory within the context of mnemonic learning. Mnemonic systems provide a convenient bridge between the theory and the study of LTM since they form the basis for the former and are also purported to enhance retention in the latter (Yates, 1966). Moreover, this interactive effect has not yet been observed with mnemonic strategies (cf. Paivio, 1968). In addition, this study examines mnemonic learning under circumstances typically employed with such techniques and ones which have not yet been subjected to empirical scrutiny. For example, nonlaboratory *S*s most often determine the rate at which items are learned, usually employ the mnemonic more than once, and expect to recall the information at some later time. Thus, the following experiment involved *S*-paced mnemonic learning of multiple lists

[1] This research was supported by U.S. Public Health Service Grant PE-00068-02 from the National Institutes of Health. The authors thank Gregory Kennington and Camille B. Wortman for their assistance in analyzing the data.

with both immediate and delayed tests of retention.

Under these conditions the 2 mediational processes should result in either differential time to master the to-be-learned information or differential retention of these items on an immediate test of retention. But, if Paivio (1969) is correct in assuming that image mediators differ in their availability, then both of these effects should not co-occur since differences in learning time should compensate for differences in immediate retention. Furthermore, if Olton (1969) is correct in that acquisition and retention (or forgetting) of information in LTM are separate processes, then these mediational sets should have no effect on delayed retention.

While mnemonic systems encompass a class of techniques, they are essentially similar in principle; one of these, in particular, has been employed in a number of experimental studies. This is the mnemonic rhyme or "peg-word" system, ONE-BUN, TWO-SHOE, ...TEN-HEN (Bugelski, 1968; Keppel & Zavortink, 1969; Paivio, 1968). This technique allows items to be learned by forming ordered pairs. For example, the first word would be memorized by associating it with the peg word BUN via a mediating image. The above studies have demonstrated that this mnemonic increases the rate of item acquisition and that imagery is essential for this to occur. Paivio developed a comparable rhyme composed of abstract words (i.e., ONE-FUN, etc.) but failed in his attempt to show its inferiority to the ONE-BUN mnemonic which is composed of high-imagery, concrete words. The following experiment seeks to evaluate the effects of these mnemonics on the acquisition and retention of information in LTM.

METHOD

Subjects and design. The *Ss* were 36 Duke University undergraduates whose participation fulfilled a course requirement. Each *S* was randomly assigned to one of 6 mnemonic acquisition conditions, so that there were 6 *Ss* per group in a $2 \times 3 \times 3 \times 2$ factorial design.

These various conditions represented 2 crossed, between-*Ss* variables, which included the abstractness-concreteness of the mnemonic rhyme pairs and mediational sets of bizarre images, common images, and verbal connections. While the 2-process theory of PA learning refers to the images usually or commonly available to and associated with concrete words, a number of studies have investigated the effects of bizarre images (Delin, 1968; Wood, 1967). Moreover, it is possible, especially under conditions where presentation time is not limited to a few seconds, that the formation of bizarre, as opposed to common, images reduces interference effects and thereby enhances recall. This would occur if such images were more elaborate and contained idiosyncratic meaning or if, as is likely, they were more differentiated and distinct than a common or ordinary image. For this reason, both of these visual imagery techniques were included along with the verbal mediation condition.

The last 2 factors in the design were composed of within-*Ss* variables. The first repeated measure included 3 lists of to-be-learned responses, and the second a temporal retention variable consisting of an immediate and delayed recall test.

Lists. Six 10-item lists of words were constructed using Paivio's tables (Paivio, Yuille, & Madigan, 1968). Three lists contained a total of 30 concrete words having a mean imagery (*I*) value (on a scale of 1–7) of 6.54 and a mean concreteness (*C*) value of 6.90. The 3 remaining lists were composed of 30 abstract words having a mean *I* value of 3.23 and a mean *C* value of 2.04. The *I* and *C* values for the 2 10-item peg-word mnemonics were approximately the same as those for the concrete and abstract word lists. All lists were counterbalanced for sequence of presentation within each 6-*S* group and for word frequency within each list.

Procedure. The procedure was patterned after Paivio and Foth's (1970) Experiment I. All *Ss* were run individually by the same *E*. Each *S* read a sheet containing a general outline of the experiment as well as providing the necessary cover story to avoid suspicion that they were returning a week later for a delayed retention test. The *Ss* then learned a number rhyme—the peg-word mnemonic. Half of them (18 *Ss*) were given the abstract rhyme—ONE-FUN, TWO-TRUE, THREE-FREE, FOUR-BORE, FIVE-LIVE, SIX-TRICKS, SEVEN-LEAVEN, EIGHT-FATE, NINE-KIND, TEN-MEND; the others learned the concrete rhyme—ONE-BUN, TWO-SHOE, THREE-TREE, FOUR-DOOR, FIVE-HIVE, SIX-STICKS, SEVEN-HEAVEN, EIGHT-GATE, NINE-WINE, and TEN-HEN. After hearing the mnemonic twice, all *Ss* were able to say it correctly aloud once and write it down twice. Each *S* was then given a sheet with appropriate illustrative examples explaining the use of the rhyme in learning word associations (by forming appropriate mediators), and containing 2 practice pairs to insure that he understood the instructions. This sequence was employed to avoid confounding learning the rhyme with using it to learn other words.

Each *S* then learned 30 words (3 10-word lists) employing one of 3 mediational methods to incorporate the list word and corresponding rhyme

word into either (*a*) a bizarre (strange or unusual) image, (*b*) a common (ordinary or usual) image, or (*c*) a sentence or phrase (verbal connection). For example, if the first word were GARDEN, the 3 mediators might be "flowers in the garden growing buns," "eating a bun in the garden," or "I saw a BUNny in the garden," respectively. Regardless of the mediational set, each *S* went through the rhyme list 3 times in learning the 30 words (i.e., one study trial for each list). The *S*s were cautioned to make each image or verbal connection distinct, thus hopefully preventing a linking together of 2 or 3 list words with the same corresponding rhyme word into one large image. To insure that *S* followed these instructions, he was required to write down (on another index card) either a description of the image mediator or the actual verbal connection. Paivio and Foth (1970) have reported that this method forces *S* to follow the particular mediational instructions.

All *S*s using the abstract rhyme learned abstract nouns and those using the concrete rhyme learned concrete nouns. The rationale for this was to avoid confounding the item attribute of the PAs with the mediational set and also to follow Paivio and Foth (1970), but with a between-*S*s mediation design. These authors noted that the interaction they found between these 2 variables may have resulted, in part, from their within-*S*s design.

Each *S* paced himself in learning the 30 words. He was given up to 1 min., if necessary, to form an appropriate image or phrase. This limit was seen as nonrestrictive since prior research (Bugelski, Kidd, & Segmen, 1968) has shown that 8 sec. is an optimal time to form an image. The *E* presented the words, one at a time, on index cards with one list following another.

Upon finishing the 3 lists, *S* was given a total recall test in which the numbers 1–10 were presented in random order, and he attempted to remember the 3 list words corresponding to the rhyme word for that number. Before ending the session, each *S* was then given 10 items from the Remote Associates Test (Mednick, 1962) to distract his attention and thus reduce rehearsal. One week later, the *S*s were given another total recall test during which they also wrote down the rhyme and all the mediators they had used to associate the peg words with the responses.

Results and Discussion

The results for the initial retention trial and their relation to the total time needed to form the associations to the rhyme words are depicted in Figure 1. Two *S*s—one in the concrete word, common image condition, and the other in the abstract word, bizarre image condition—failed to return for the delayed retention test, and their data were not included in the analysis. The mean numbers of words ini[illegible] re-called with both common an[illegible]rre imagery and verbal mediators, res[illegible]ely, were 23.8, 23.7, and 24.7 for concr[illegible]ns, and 15.2, 16.8, and 16.0 for abstra[illegible]ns. A univariate analysis of variance [illegible]med the usual highly significant main [illegible] for the item attribute of the mnemo[illegible]me pair (i.e., abstract or concrete), [illegible] 28) $= 25.33$, $p < .001$. As in Wood [illegible]peri-ments (1967), no differential effe[illegible] re-call was found for mediational se[illegible]e or interacting with the mnemonic rh[illegible] pair conditions (Fs < 1). However, [illegible] pre-dicted, the *S*s did take different a[illegible]ounts of time to acquire the same num[illegible]er of items, F (2, 28) $= 5.85$, $p < .01$. The bizarre images, not unexpectedly, took significantly longer to generate than either the common, F (1, 28) $= 5.18$, $p < .05$, or the verbal mediators, F (1, 28) $= 11.28$, $p < .01$, since they were not as readily available.

These findings appear to preclude differential overlearning resulting from self-pacing as a possible explanation. Where there were differences in pacing as in the mediation conditions, there was no difference in performance. But, this is precisely the situation in which such differences due to overlearning (i.e., having more study time) would be predicted. On the other hand, there was no difference in total learning time between abstract and concrete conditions ($F < 1.5$), but there was a large difference in retention. Similarly, the ability of all *S*s to learn the mnemonic rhyme perfectly on the first trial and to recall it correctly 1 wk. later seems to preclude differential overlearning of the rhyme and subsequent transfer effects as an explanation for these findings.

These results, moreover, clearly support the 2-process theory of verbal learning. There was a significant interaction in total learning or acquisition time between item attribute and mediational set for common images and verbal associations, F (1, 28) $= 5.33$, $p < .05$. The contrasts yielded the expected pattern with common images taking significantly longer to generate than verbal mediators for abstract nouns, F (1,

28) = 5.85, $p < .05$. On the other hand, the difference was not significant for concrete nouns ($F < 1$). Similarly, common images took less time to generate (i.e., they appear more available) for concrete than abstract words, F (1, 28) = 4.15, $p < .05$, while verbal connections were equally available for both ($F < 1.5$). The interaction, contrasts, and simple effects confirm both 2-process theory predictions of a trade-off between acquisition time and recall performance and the differential availability of imaginal mediators for concrete and abstract nouns.

On the delayed retention test 1 wk. later, the mean numbers of words recalled with both common and bizarre imagery and verbal mediators, respectively, were 16.2, 15.2, and 15.7 for concrete nouns, and 7.3, 8.0, and 8.2 for abstract nouns. A highly significant main effect was found for the retention variable, F (1, 28) = 118.73, $p < .0001$, indicating a large amount of forgetting during the week separating the 2 recall trials. In fact, this loss in retention was approximately constant for all conditions (about 8.2 items), showing no effects for either mediational set or item attribute (Fs < 1). Given the rather large initial differences in retention between abstract and concrete noun pairs, this constant forgetting resulted in a differential rate of forgetting (50% and 35%, respectively). However, this did not produce a significant interaction over the 2 retention trials ($F < 1$).

This supports Olton's results (1969) indicating that acquisition and retention in LTM are separate processes with mnemonic encoding affecting the former, but not the latter, process. Moreover, this constant forgetting contradicts Bower's (1972) notion that the decay rate in LTM is faster for verbal mediators than for imaginal ones. Instead, it necessitates a clear distinction between availability and decay. The former affects acquisition and the latter retention; and as these data indicate, it is mediator availability in mnemonic learning that reflects the interaction of associative techniques and item type. Moreover, the similarity and consistency of the between-Ss findings for item attribute

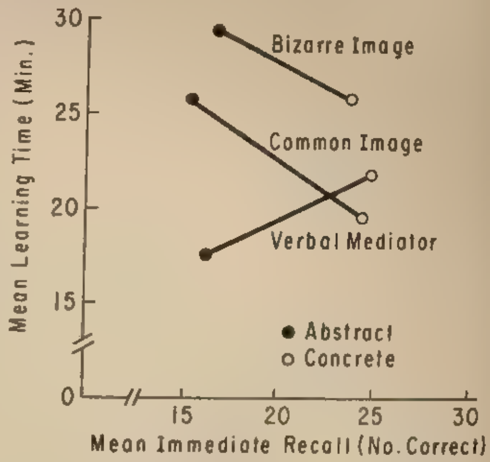

FIGURE 1. Mean immediate recall and learning time as a function of item concreteness abstractness and mediational technique.

and mediational set over the 2 retention tests indicate the absence of differential effects on the second trial resulting from the first retention probe.

There is, in addition, no differential or learning-to-learn effect for the 3 lists ($F < 1.5$). It is possible, however, that the amount of forgetting from LTM was overestimated due to a procedural error. Since the first recall test followed immediately after the study trial for the third list, with no interpolated activity, not all of the items recalled may have been in LTM. The mean amounts of forgetting from the 3 lists were 2.2, 2.5, and 3.6 items, respectively. This produced a significant List × Retention Trial interaction, F (2, 27) = 9.17, $p < .01$, with forgetting from List 3 significantly greater than that from the other 2 lists, both Fs (1, 28) > 6, $p < .05$. Thus retention was underestimated by approximately one item—a relatively small effect compared with the large number forgotten. Finally, while mediator availability has been found to be an important factor in the acquisition or encoding of an item, it is also possible that mediator decodability affects performance. An analysis of the missed items on the delayed recall trial revealed that it was more difficult to decode the responses from abstract mediators (a mean of 3.0 items not de-

coded) than concrete mediators (a mean of 1.2 undecoded items), $F(1, 28) = 7.53$, $p < .05$.

Conclusions

The results of this study indicate that when (mnemonic) learning is S paced instead of E paced, there is a trade-off in the performance for acquisition or learning time. That is, S-paced learning results in differential rates of acquisition for various mediating strategies but not in differential performance, while the reverse is true in E-paced studies (where the presentation rate is typically less than 15 sec.). The availability hypothesis that common images are more readily evoked by concrete than abstract nouns, with no such difference occurring with verbal mediators, was also supported. While these findings are in agreement with Paivio's (1969) 2-process theory of verbal learning, the relatively large effects on recall due to abstractness–concreteness, despite the S-paced differences in acquisition rate, indicate that a modification of theory is necessary. The factor of item attribute absolutely affects performance independent of presentation rate, and as such is prepotent; while mediational set primarily affects the information-processing rate (i.e., item acquisition in LTM) and only incidentally (i.e., at fast presentation rates) the performance of the learning system.

A RATIO RULE FROM INTEGRATION THEORY APPLIED TO INFERENCE JUDGMENTS[1]

MANUEL LEON[2] AND NORMAN H. ANDERSON

University of California, San Diego

The *S*s judged the likelihood that a sample had come from 1 of 2 binary urns of specified proportions of red and white beads. The compositions of the sample and of the 2 urns were varied in a 3-way design. A ratio model from integration theory fit the data quite well. The response is treated as a resultant of 2 competing response tendencies that reflect the felt likelihoods that the sample comes from either urn. A novel application of analysis of variance for nonlinear models was employed in the test of fit. Relations to Bayesian theory, choice theory, representativeness, as well as previous work on serial integration by J. C. Shanteau and T. S. Wallsten, were discussed.

This report considers the 2-urn task that has been used in much of the experimental work on the Bayesian approach to decision making. A single sample was drawn from 1 of 2 specified binary urns, of 80/20 and 40/60 composition, for instance, and *S* judged the probability that the sample had come from the 80/20 urn. However, instead of applying the Bayesian statistical model (Edwards, 1968; Slovic & Lichtenstein, 1971), the present report follows the lead of Shanteau (1970, 1972) in seeking a descriptive, psychological model for subjective inference.

In preliminary work, conversation with *S*s suggested that their judgments were based on a comparison between the 2 probabilities that the sample came from either urn. On that basis, the overt response is considered as a compromise between 2 covert response tendencies. Upon seeing the sample, *S* evaluates the subjective probabilities that it comes from either urn. These 2 response tendencies then determine the actual response. The specific question at issue is the integration rule that governs how the 2 response tendencies combined.

Two particular integration rules suggested themselves. One was a subtracting model from conflict theory (Anderson, 1962b). The 2 competing response tendencies would be conceptualized as approach and avoidance tendencies; the effective response would equal the difference in their strengths.

The other integration rule derives from averaging theory (Anderson, 1974). Each covert response tendency would be assumed to have a scale value and a weight, e.g., s_1 and w_1 for the more likely urn, s_2 and w_2 for the less likely urn. The response is then the weighted average:

$$R = (w_1s_1 + w_2s_2)/(w_1 + w_2). \quad [1]$$

In the present task, the scale values may be specified as $s_1 = 1$, $s_2 = 0$, since these represent the end points of the decision scale. Equation 1 then reduces to

$$R = w_1/(w_1 + w_2). \quad [2]$$

Equation 2 is a ratio rule: The overt response is the ratio of the strength of 1 response divided by the sum of the strengths of the 2 responses. This ratio rule can be generalized directly to the case of several competing responses, corresponding to several possible parent urns. In this situation, therefore, integration theory leads to a ratio rule similar to that used by Luce (1959) and others. Unlike Luce's choice theory, however, integration theory

allows deterministic numerical response measures.

In testing such algebraic models, functional measurement methodology typically employs factorial designs. An attempt was made in the present experiment to avoid any assumptions about relations among samples of different composition. Accordingly, single samples were used, and the factors of the design were the compositions of the more likely urn and of the less likely urn, a device also used by Wallsten (1972). The subtracting model then predicts a zero between-urns interaction in the analysis of variance (Anderson, 1962b). The ratio model is nonlinear and not testable so simply. However, an important new test procedure was developed that may be generally useful in the analysis of nonlinear models.

Method

On each trial, *S* saw a single sample of red and white beads and 2 binary parent urns. His task was to choose the more probable urn and then make a graphic rating "to indicate on the scale how likely it is that you are correct."

Design

The main experimental design was a 3 × 4 × 8 factorial. There were 3 levels of the *less probable urn* in which the red/white ratios were 10/90, 20/80, and 40/60. There were 4 levels of the *more probable urn* in which the red/white ratios were 60/40, 70/30, 80/20, and 90/10. Finally, there were 8 *samples:* 4 homogeneous, with 1, 2, 3, or 4 red beads, and 4 mixed, with 3/1, 4/1, 3/2, and 6/2 red/white ratios. This design was balanced over red and white to yield 192 judgments. In addition, 16 extreme anchor sets were included.

An auxiliary design was also employed in which the parent urns were 70/30 and 30/70 for all samples. There were 100 samples, which included all possible red/white ratios in which the number of red and white beads each varied from 1 to 10. Four additional extreme anchor sets were also used in this condition.

Procedure

Each urn was represented by a transparent plastic bag with 100 beads in the specified proportion, together with a numerical label, such as 60/40, to indicate its contents. On each trial, an index card was presented on which the 2 relevant urns were listed (e.g., 60/40 and 20/80), and on which the sample was represented by rows of large red and white dots, one color in each row.

Responses were made by placing a pin in a [illegible]-cm. scale, read from the rear by E. The right and left halves of the scale were used to indicate likelihood judgments of the mostly red and the mostly white urns, respectively, with the center of the scale corresponding to equally likely.

The judgments were collected in the following 4 consecutive stages: (*a*) preliminary instructions followed by a practice phase which included the 16 anchor sets plus 64 sets from the main design, (*b*) the 16 anchors plus the 192 sets from the main design, (*c*) the 104 judgments of the auxiliary design, and (*d*) direct judgments of the likelihood of each of the 8 samples coming from each 1 of the [illegible] urns used in the main design. These last data did not seem very useful and are not reported here. Except for practice, the deck of index cards was shuffled separately for each *S* for each stage. Stimulus cards were presented at approximately one every [illegible] sec.

The *S*s were 24 introductory psychology students who served as part of a course requirement. Each served in a single session of approximately [illegible] min. with a 5-min. rest after the main design.

Results

Empirical Results

Main design. Each curve in Figure 1 shows the mean response to 1 of the 8 samples, plotted as a function of the more probable urn. The 2 main trends are as expected: the likelihood judgment increases (*a*) as the composition of the more probable urn becomes more extreme, and (*b*) as the difference between red and white beads in the sample becomes more extreme. The main effects of these 2 variables were highly significant, *F*s $(3, 69) = 72.55$ and 36.92, as was also the effect of the less probable urn, $F\ (2, 46) = 58.11$.

Neither the difference between red and white, nor the ratio of red to white, is the sole determinant of judged likelihood. First, to each homogeneous sample in the left panel there is a corresponding mixed sample in the right panel that has the same difference between red and white. Since the 2 sets of curves have different overall shape and elevation, the response is determined by more than the difference between red and white. Second, the curve for the 6/2 sample is substantially higher than for the 3/1 sample. Thus, the response is determined by more than the sample ratio. Supporting evidence is given in the next subsection.

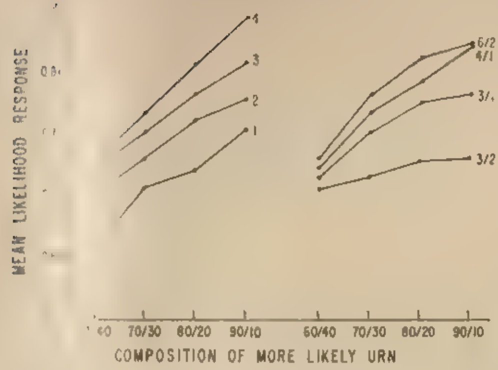

FIGURE 1. Mean likelihood judgment as a function of the composition of the more likely urn, and of sample composition as listed by each curve. (Data averaged over less likely urn.)

Special theoretical significance attaches to the case in which the 2 urns have symmetrical red/white proportions. From the Bayesian model, the statistically optimal response then depends only on the difference between red and white. Descriptive models might also embody such an assumption on the ground that each red–white pair of beads is uninformative and would be ignored. Because of the theoretical significance of these data, they are presented separately in Figure 2.

The relevant comparison in Figure 2 is between the left and right panels. They should be identical if the response is determined by the difference between red and white. But in fact the 2 panels differ considerably. The response to homogeneous samples is more extreme in either direction, and covers a greater vertical range. Also, the mixed samples show no effect of set size for the 60/40 urn pair. That the 2 panels are reliably different is shown by the Sample Type × Urn Composition interaction, F (2, 46) = 6.65.

Auxiliary design. In this design, the 2 urns were complementary, of 70/30 and 30/70 composition. All 10 × 10 possible samples, with 1–10 beads of each color, were used. Illustrative data are shown in Figure 3.

In the left panel of Figure 3, the near identity of the 3 curves shows that the response was completely governed by the difference between the number of red and white beads in the sample (plotted on the horizontal). At any point, the curves represent samples that have the same difference between red and white, though differing in sample size. The curve labeled 9 + 10 is averaged over the samples in which there were 9 or 10 beads of the dominant color. The curves labeled 7 + 8 and 5 + 6 were obtained similarly. It was not feasible to plot all the data points because they all lay on top of one another. As these curves show, however, sample size per se had no effect in this phase of the experiment.

The same conclusion is illustrated in different form in the right panel of Figure 3. The solid curve represents the 5 samples with a 1/2 ratio. The dashed curve represents the 3 samples with a 2/3 ratio. The upward trend shows that something more than the sample ratio controls the response. The near equality of the 2 curves illustrates again that the sample difference is the controlling factor.

The data from this auxiliary design should be interpreted cautiously. The very simplicity in the pattern of results suggests that Ss may have adopted a cancellation strategy. Canceling red against white would lead to the obtained results. Since the 2 urns were complementary and fixed over all trials, Ss could devote their attention to the characteristics of the sample itself.

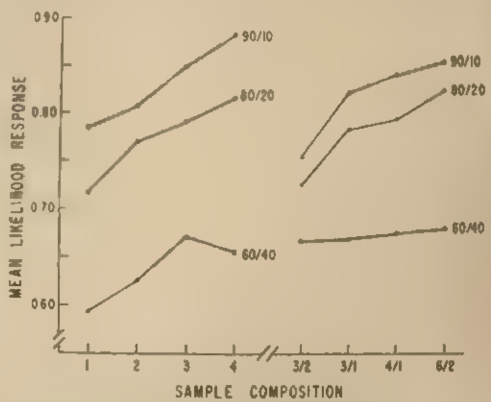

FIGURE 2. Mean likelihood judgment as a function of sample composition and urn composition. (Data for symmetrical urns only.)

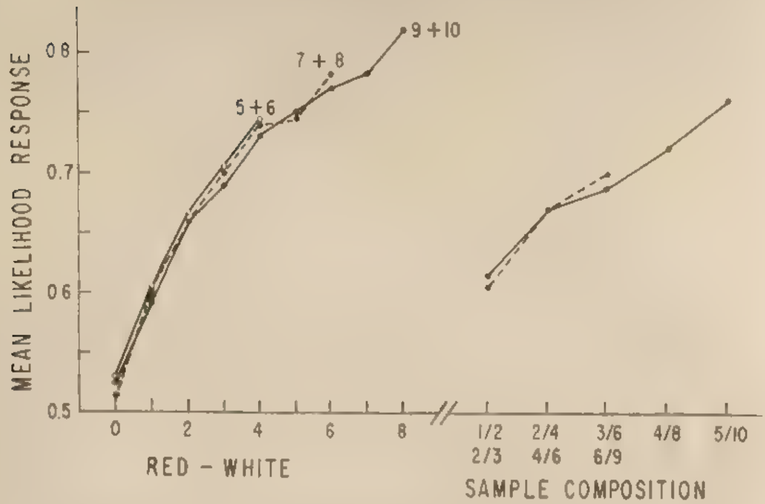

FIGURE 3. Mean likelihood judgment from the auxiliary design with 70/30 and 30/70 urns.

In the main design, such a cancellation strategy would seem less appropriate. In fact, the difference between the left and right panels of Figure 1 shows that something more than the sample difference controlled the response. That was true even for the cases in which the urns were symmetric as already noted. Deviations from the difference rule were moderately small, however, so it may be a good first approximation.

Model Analysis

Model predictions. Figure 4 plots mean likelihood response as a function of the more and less likely urns. The left and right panels are averages over the 4 homogeneous samples and the 4 mixed samples, respectively.

The curves in Figure 4 are theoretical, obtained by fitting the ratio model of Equation 2 as described below. The fit is quite close which supports the ratio model.

An additional aspect of Figure 4 is the nonparallelism of the data points in each panel. A model that assumed 2 response tendencies that combined by a subtracting rule would predict parallelism. That the observed nonparallelism is reliable is shown by the significant More Likely Urn × Less Likely Urn interaction, $F(6, 138) = 2.99$. Wallsten's (1972) data, converted from odds to probabilities, show the same shape, with an even more marked interaction. On the face of it, therefore, a subtracting model does not account for the data.

Figure 4, incidentally, illustrates an optical illusion that affects apparent parallelism, as the data seem more parallel than they are in fact. The vertical spread of data points for the 60/40 urn is greater than for the 90/10 urn by about 75% for the homogeneous samples and 30% for the mixed samples. In making graphic assessments of parallelism, it is often helpful to turn the graph sidewise and measure the physical distances.

Weight estimates. Figure 5 plots mean weight estimates from the ratio model as a function of urn and sample composition. The trends can be understood most easily by reference to the theory, in which the values of w_1 and w_2 represent the response strengths of the 2 alternatives.

Theoretically, therefore, w_1 should increase as the composition of the more likely urn becomes more extreme, and also as sample composition becomes more extreme. Both trends are quite marked.

The trends for w_2, in contrast, are much less marked. A mild effect of the composition of the less likely urn can be seen, but

the effect of the sample was so small that the points could not be graphed separately. To a first approximation, therefore, the less likely urn appears to have a nearly constant response strength.

Estimation and goodness of fit. The model was tested by a novel and potentially important application of functional measurement methodology. Since Equation 2 is nonlinear, the parameter estimates are not statistically independent, and the number of degrees of freedom used in the estimation is unknown. If only relatively few parameters were estimated, the rule of one degree of freedom per parameter would presumably be an adequate approximation. Even so, there would be a difficult problem of incorporating the variabilities of both the observed and the predicted data points in the test. In general, exact analysis of nonlinear models is not easy.

The method developed here may bypass all these difficulties in a simple way. Chandler's (1969) STEPIT routine was applied to estimate the weight parameters of Equation 2 for each of the 8 samples for each *S*. The means of these estimates were used in Figure 5. Predicted responses were also generated for each of the 8 samples for each *S* by using these weight estimates in Equation 2. The means of these predicted responses were used in Figure 4.

To test goodness of fit, the predicted responses were subtracted from the observed to yield deviation scores. The data for statistical analysis are thus the 8 3 × 4 matrices of deviation scores for each *S*.

These deviation scores were analyzed in an ordinary repeated-measurements analysis of variance. The homogeneous and mixed samples were treated separately so that there were 2 3-way analyses of variance. If the model is correct, then these deviations should be no more than chance. The *F* ratios in Table 1 should cluster around 1 and none should be significant. In fact, 1 of the 16 is significant, but that is

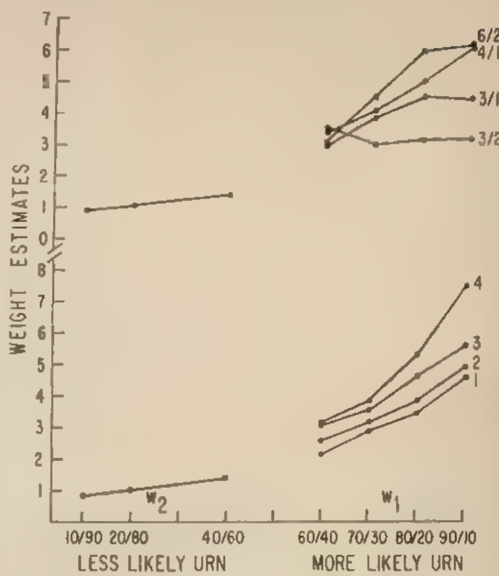

FIGURE 5. Response strengths of more and less likely choice alternatives.

TABLE 1

SUMMARY ANALYSES OF VARIANCE OF DEVIATIONS FROM RATIO MODEL

Source	*df*	Homogeneous samples		Mixed samples	
		F	Error	*F*	Error
Mean	1	1.36	.2568	1.22	.1169
Samples (S)	3	.45	.1294	1.78	.1069
Less likely urn (LLU)	2	1.60	.7615	1.13	.4058
More likely urn (MLU)	3	.82	.7956	1.00	.5465
S × LLU	6	1.21	.4683	1.63	.3571
S × MLU	9	1.02	.3685	.95	.3741
LLU × MLU	6	.75	28.2653	.61	21.1473
S × LLU × MLU	18	1.15	18.3115	2.01*	17.9208

Note. Error mean squares have 23 times as many degrees of freedom as corresponding systematic source. Error mean squares multiplied by 10,000.
* $p < .05$.

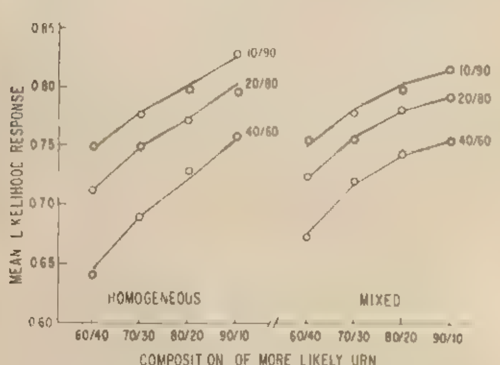

FIGURE 4. Predicted and obtained likelihood judgments. (Curves are theoretical, from ratio model. Data points averaged over 4 samples in each panel.)

about the chance expectation with 16 tests. Thus, this goodness of fit test supports the model.

This test may be disturbing because a good fit is guaranteed by using 7 parameters to fit 12 data points. However, the error term is itself composed of the small deviations from that good fit. Thus, the test should be sensitive even to small discrepancies if they are systematic across *S*s.

The main technical problem in this test is that the predicted scores, and hence also the deviation scores, are not independent but are correlated through their joint dependence on the estimated parameters. However, the analysis of variance for repeated measurements allows for correlated scores (Winer, 1971, p. 279).

Two comments may help relate this test to the ordinary applications of analysis of variance. First, any linear contrast on the deviation scores would have an exact t test, obtained by comparing its mean to its variability across *S*s. Applied to main effects or interactions on one degree of freedom, this t test would be equivalent to the above F test. Second, if the present method were applied to an additive rather than a nonlinear model, it would be equivalent to the ordinary analysis of variance except that all main effects would necessarily be zero.

Tests based on group data are sensitive to discrepancies that are systematic across *S*s. However, real discrepancies at the individual level may get overlooked if they are idiosyncratic. Table 1 contains a warning in this regard since the error mean squares for the last 2 interactions are much larger than for the others. Since the error term for each listed source is its interaction with *S*s, the size of these errors suggests that there may be real discrepancies though of different form for different individuals.

The present method could be applied directly to single *S*s by replicating the experiment several times. These replications would be treated exactly as *S*s in the present analysis. The deviation scores within each replication would be correlated, but such correlation is allowed in the given analysis.

This method for testing goodness of fit is presented tentatively. If it is supported in further work, it could be extremely important because it provides an exact analysis for nonlinear models. An especially interesting possible application is to response scaling. Thus, the test could be used to provide an error theory for nonmetric approaches, such as used in conjoint measurement (Krantz, Luce, Suppes, & Tversky, 1971), or Kruskal's (1965) monotone analysis of variance, for which an error theory is presently lacking (see Weiss & Anderson, 1972). In such applications, the test would be made on the differences between the monotonically transformed data points and the best-fit additive representation.

Discussion

Ratio Model

The basic assumption of the present approach is that the overt response is a compromise between 2 competing response tendencies. One specific integration rule considered here was the ratio rule from averaging theory, i.e., that the overt response was the average of the 2 competing response tendencies. This ratio rule gave a good account of the data and led to meaningful parameter estimates. The strength parameter for the less likely urn was approximately constant over conditions, as though it exerted much the same effect regardless of its composition or the composition of the sample. In contrast, the strength parameter of the more likely urn varied markedly across conditions, suggesting that this urn was given the main attention.

An alternative, the subtracting model, was also considered in which the overt response is just the difference between the 2 response strengths. Interestingly enough, the ratio and subtracting models cannot be distinguished in the present experiment as they are monotonically equivalent. If R obeys a ratio model, then $\log(R^{-1} - 1)$ obeys a subtracting model. Since functional measurement methodology allows for monotone response transformation (Anderson, 1962b), the present data do not allow the conclusion that the ratio model is superior to the subtracting model. Either might be correct.

Some preference may be expressed for the ratio model because it fits the raw data,

whereas response transformation would be required for the subtracting model. Previous work on functional measurement has shown that raw ratings are often near-interval scales and that argues for the tentative acceptance of the ratio model. On the other hand, parameter estimates for the 2 urns would be more comparable under the subtracting model.

The ratio model and the subtracting model are not monotonically equivalent in general. For 3 or more urns, the ratio model is inherently nonlinear in the sense that no monotone transformation will make $w_1/(w_1 + w_2 + w_3)$ linear in all 3 variables at once. The subtracting model, $w_1 - w_2 - w_3$, remains linear, at least in form.

A limitation on the applicability of at least the ratio model is suggested by the marked difference between the 2 weight parameters obtained here. Whereas the weight parameter for the more likely urn showed a strong dependence on the stimulus variables, the weight parameter for the less likely urn was almost constant. This suggests that the parameter valuation process may be configural, influenced by attentional factors. To ensure constant parameters, it would thus seem advisable to keep the same urn predominant in all cases.

Choice Theory

Although the ratio model of integration theory has the same form as Luce's (1959) choice model, there are several basic differences between them. The most important of these center on the difference between choice probabilities and numerical response measures. Luce's model applies, in effect, only to imperfect discrimination, or probabilistic threshold choices. In contrast, integration theory deals with numerical-valued response strengths, and applies even when there is no probabilistic element in the choice.

This difference is well illustrated in the present task, in which the appropriate response is never in doubt. Unless the sample is split evenly, the appropriate choice of urn is specified by the majority proportion in the sample. Since the choice probabilities are 0 or 1, Luce's formulation does not apply.

Whether the present averaging model might be applicable to threshold choices is uncertain. Substantively, if not formally, that would seem to require that the actual choice process can be conceptualized as an averaging process even in the case of imperfect discrimination. Some evidence that supports this idea is given by Friedman, Carterette, and Anderson (1968), Friedman, Rollins, and Padilla (1968), Himmelfarb (1970), Robbins and Medin (1971), and Levin, Dulberg, Dooley, and Hinrichs (1972).

Bayesian Theory

The Bayesian approach is similar to integration theory in its emphasis on problems of combining information to reach a judgment. The wide use of the 2-urn task reflects the pioneering efforts of the Bayesian workers in studying how information is integrated in decision making.

In a strict sense, comparison of these 2 approaches is not appropriate. Integration theory is a descriptive psychological theory, whereas the normative Bayesian model derives from mathematical statistics and prescribes the optimal response in an actuarial sense. In various practical applications, knowledge of the optimal, normative response can be most important.

Almost inevitably, however, normative models are forced into a descriptive mode for which they are ill-suited. Thus, a dominant concern in the Bayesian work has been with explanations of "conservatism," the general tendency for the response to be less extreme than the optimal response. Conservatism was obtained in the present experiment also, but no attempt has been made to explain it because there is nothing to explain. Conservatism is not a phenomenon, only a name. It exists only by reference to a statistical model that has no psychological relevance. "Explanations" of conservatism in terms of misperception, misaggregation or response bias are inappropriate because there is no psychological phenomenon to be explained.

To be fair to the Bayesians, it should be repeated that conservatism can be important in practical applications in which there is a cash value on correct responding. Pursuing such problems in the experimental laboratory can be quite useful. Nevertheless, commitment to the study of optimal behavior is not innocuous. It has diverted attention from the actual behavior, as is implied by the papers of Shanteau (1970, 1972), Slovic and Lichtenstein (1971), Wallsten (1972), and Anderson (1971, p. 195). In particular, the data reported in the Bayesian studies are ordinarily derived statistics, calculated from the Bayesian model itself, so that identical behavior in different conditions will produce different derived

statistics. Such data analysis makes it hard to understand what *S*s actually did.

Representativeness

Kahneman and Tversky (1972) have argued from a heuristic of sample-population "representativeness" that the response to single samples in the Bayesian task should be controlled almost entirely by the sample proportion. In particular, they claim that the response should be virtually independent of the sample size, and independent of the urn proportions (pp. 446, 450). The data of their Table 1 support their claim since the responses are very nearly equal to the actual sample proportions.

The present results differ radically from those of Kahneman and Tversky (1972). Figures 1, 2, and 4 show a very strong effect of the urn proportions, in agreement with the results of Shanteau (1972) and Wallsten (1972). Further, the right panels of Figures 1 and 3 show a strong effect of sample size with sample proportion held constant. In both respects, therefore, the present data disagree with those given by Kahneman and Tversky.

The simplest explanation of this difference is that Kahneman and Tversky (1972) failed to make their task clear. Their *S*s were run in large classroom groups in 1 or 2 min. of a regular class session, and each *S* judged only one problem. That the task was not clear is suggested by the fact that about 10% of the *S*s had to be eliminated (pp. 432, 447). It hardly seems surprising, therefore, that their *S*s might have failed to understand the task and simply interpreted their job as one of judging the sample proportion.

A warning on this problem was sounded by Shanteau (1970) who found no difference between estimation and inference instructions with serial presentation. Logically, these 2 instructions should produce quite different behavior, with the inference group tending toward 0 or 1, and the estimation group toward the prevailing proportion. The lack of difference was surprising, therefore, yet it was replicated in a follow-up experiment in which Shanteau used special care in explaining the judgment task to *S*s.

Shanteau's (1970) results indicate that *S*s in the Bayesian task are not making inference judgments, as has been assumed in tests of the Bayesian model. Instead, they appear to be doing something qualitatively different, more akin to estimation. This illustrates an important methodological point that appears to be especially relevant to judgment theory. The meaning of a response is not given simply by the words that the investigator uses, but rather by the network of empirical relations that surround the behavior.

Simultaneous Integration

The present work is most closely related to that of Shanteau (1970, 1972) and of Wallsten (1972). In all this work, primary emphasis is on the algebraic rule or psychological law that governs the integration of the information. Wallsten attempted to develop a descriptive analogue of the Bayesian model, whereas Shanteau employed a model derived from information-integration theory. Shanteau was mainly concerned with serial integration which is discussed below. Simultaneous presentation, as used here, seems to involve different processes and requires a few preliminary comments.

A basic question for simultaneous presentation is whether the effect of the set of stimulus information can be represented as a simple function of the elements of the set. Considerable evidence for this view has been obtained in person perception and various other tasks (e.g., Anderson, 1962a, 1967, 1974).

In the 2-urn task, a similar view has been taken by Shanteau (1970, Equation 3) and by Wallsten (1972). In particular, Wallsten's multiplying assumption implies that the difference between the number of red and white beads is the only relevant property of the sample for the special case of symmetric urns. This follows from Wallsten's Equation 3a, together with the added assumption that a sample split evenly between red and white has no effect when the urns are symmetric.

Unfortunately for the 2-urn task, the present data indicate that the effect of the sample is not a simple function of its elements. The qualitative test of Figure 2 shows that the difference between red and white is not the sole determiner of the response. Sample composition appears to have a gestalt effect. The data from the auxiliary design (Figure 3) did obey a cancellation property, but that may reflect a more deliberate strategy potentiated by special task conditions. Shanteau's (1970, Figure 4) data also imply that the effect of a simultaneous sample is not a simple function of its elements. This problem, it should be noted, did not arise in Shanteau's results with serial presentation, but he used only one-bead samples.

Serial Integration

Two basic reports by Shanteau (1970, 1972) have studied behavior in the Bayesian task using sequences of one-bead samples. A serial integration model gave a very good account of the data whereas the Bayesian model did poorly. A surprising result, noted above, was the lack of difference between estimation and inference instructions. This result caused a serious conceptual problem for the Bayesian formulation because the evidence suggested that *Ss* were doing something akin to estimation regardless of the instructions.

However, Shanteau's (1970, 1972) success with the observed behavior obscured a theoretical difficulty with his model as applied to inference rather than estimation. No problem arises if the same sample is presented at each serial position; unless it was split evenly, the response would always asymptote at 0 or 1. However, that would not necessarily happen if sample composition varied across serial position. In particular, a sequence of random samples of single beads from any urn would asymptote at the urn proportion. Despite its success, therefore, the serial integration model used by Shanteau would not seem able to handle general inference judgments without further elaboration.

Wallsten (1972) has also attempted to develop a model for serial integration. However, it has been worked out explicitly only for the case of a sequence of identical samples, and in that form it is effectively equivalent to the serial integration model used by Shanteau. Wallsten's approach seems more general since it explicitly allows for monotone response transformation, but the functional measurement methodology used by Shanteau has the same capability. Since Shanteau's analysis showed that the untransformed response was already an interval scale, response transformation was not needed. Wallsten's nonmetric, ordinal analyses did not allow a satisfactory test of the basic model.

The present formulation deals explicitly only with a single sample, and it is uncertain how it should be extended to handle serial integration of successive samples. Three possibilities deserve mention. The first is that separate cumulative counts of the red and white beads are maintained, and that the 2 competing response tendencies are recomputed from the cumulative counts after each successive sample. In effect, this reduces the serial case to the simultaneous case. However, it would allow serial position weights for each separate count so that serial position effects could be allowed for.

The second possibility is similar to the first, but allows only one counter which cumulates the difference between red and white. Weighting as a function of serial position would be allowable, but a cancellation strategy would be required within any single sample. Cancellation is not entirely consistent with present results, though it might provide a reasonable first approximation.

The third possibility is that each later sample sets up 2 competing response tendencies in exactly the same way as with the first sample. These are then averaged in with the single resultant response produced at the previous serial position. The resultant would have a scale value of 0 or 1, and a weight that would reflect the total amount of information.

Concluding Comments

Three theoretical problems are basic in the analysis of the 2-urn task. The first problem concerns the integration model for a single sample. Present data give some slight preference for the ratio model over the subtracting model, but a critical test between them remains to be done.

The second problem is how the response to any sample relates to its component elements. Unfortunately, as noted above, this problem may not have a simple solution like that found for verbal stimuli. Present data indicate some departure from the simple cancellation strategy even with symmetrical urns.

The third problem is that an adequate general theory must handle serial presentation as well as simultaneous presentation. Serial presentation involves additional complications, however, and it may be desirable to place greater attention on the first 2 problems which have been relatively neglected in previous work.

ROLE OF CENTRAL MONITORING OF EFFERENCE IN SHORT-TERM MEMORY FOR MOVEMENTS

BILL JONES[1]

University of Queensland, St. Lucia, Brisbane, Queensland, Australia

A necessary and sufficient condition for retention of movements over a short time interval may be central monitoring of efferent signals to the muscles (CME) rather than proprioceptive feedback (PFB). It is shown that voluntary movements may be rehearsed over a 15-sec. unfilled retention interval even when location cues are removed, whereas passive movements and constrained movements—movements made to a stop set by *E*, which B. Jones has shown may not be centrally monitored—are subject to decay. Voluntary movements are affected only by an attention-demanding task during the retention interval. Since augmented PFB does not increase accuracy of voluntary movement duplication, CME may be a necessary and sufficient condition for rehearsal in motor short-term memory.

If we are to describe a pattern of movements as skilled, the component movements must at the least be carried out in the correct temporal sequence. Such timing could conceivably depend upon peripheral feedback or may result from central monitoring of efferent commands to the muscles (CME). The present article is concerned with the role of CME compared with proprioceptive feedback from joints and/or muscles (PFB) in short-term retention of single movements (MSTM). Since even the simplest voluntary act requires the regulation of at least 2 antagonistic muscle groups coupled at a joint, timing is a feature of MSTM.

Posner (1967) showed there is little forgetting of visually guided movements over an unfilled retention interval of 20 sec. although an attention-demanding task during the interval did interfere with performance. When *S*s were blindfolded, on the other hand, considerable forgetting occurred after 20 sec. and the interpolated task had no further effect. Posner (1967) argued that central processing capacity is available to the visual channel which functions as a "rehearsal" mechanism and that absence of such capacity makes little difference to the retention of kinesthetic information, even if the interpolated task requires movements as in writing (Posner & Konick, 1966).

However, some movements, including replications of the standard movement during the retention interval (Stelmach & Bassin, 1971), do interfere with MSTM for blind movements. Keele (1968), therefore, suggested that duplication of some movements may be based upon PFB from the muscles, which is not rehearsed, whereas input from the joints has access to central storage and hence may be subject to interference. He did not consider whether CME may be involved, and his PFB argument rests in any case on 2 invalid assumptions.

First, Keele (1968) assumes that only afferents from joint receptors project to the sensory cortex. This is not the case in the monkey and the cat and there is no reason to think that it is the case in man (see Paillard & Brouchon, 1968). The second implied assumption is that the joint receptors signal direction and extent of voluntary movement. However, while we know that joint receptor impulses mediate knowledge of *passive* movements and that the muscle spindles are not involved here (see Rose & Mountcastle, 1959), there is clear evidence that voluntary movements may be accurately duplicated when the joint capsule is anesthetized, thus eliminating joint feedback (Browne, Lee, & Ring, 1954). We can argue, therefore, either that the duplication of voluntary

[1] Requests for reprints should be sent to Bill Jones, who is now at the Department of Psychology, University of Waterloo, Waterloo, Ontario, Canada.

movement is based upon CME or that PFB from the muscle spindles is tied in with voluntary but not with passive movement (Browne et al., 1954; Paillard & Brouchon, 1968).

Jones (1972) attempted to test the alternative hypothesis by comparing the ability of blindfolded *S*s to produce a voluntary movement based upon one of 3 initial movements. Either (*a*) *S* made a voluntary movement, (*b*) *S* moved to a stop set by *E* ("constrained movement"), or (*c*) *S*'s arm was passively moved to the stop ("passive movement"). There was little difference in voluntary duplication of constrained and passive movements, which were duplicated with significantly less accuracy than were voluntary movements. Jones argued that only in the voluntary condition could *S* predict the end point of the initial movement before he began to move, so that only here was retention mediated by CME. Since both voluntary and constrained conditions required maintenance of muscle tone during the initial movement, there is no reason to think that the behavior of muscle spindles in the 2 movements would have differed; and yet without the opportunity to make a preset movement, reproduction accuracy decreased to the level of passive movement. It may be that both passive movement and constrained movement are based upon joint inflow, or that duplication of constrained movement requires such a complex integration of CME over sections of the movement that the initial movement did not lay down an adequate trace. In any case, there is evidence against the hypothesis of spindle involvement in voluntary movement and in favor of the CME position.

The hypothesis tested in Experiment I is that the initiation of a voluntary movement results in a central record of efferent discharge, or "efferent copy" (von Holst, 1954), which is in itself a motor memory storage system without the requirement of peripheral feedback. Since the efferent copy is central it may be subject to interference, unlike PFB which has no access to central mechanisms. In other words, CME is a necessary condition for rehearsal in MSTM.

Experiment I

Most previous studies of motor retention have had *S*s duplicate a constrained movement and so may have provided little opportunity for retention via CME. The first experiment compared retention of voluntary, constrained, and passive movements over both filled and unfilled retention intervals. The main measure of movement reproduction accuracy was variable error (VE)—mean within-*S*s standard deviation about the algebraic mean. Many other studies of movement duplication (including my own) have had absolute error (AE) as the dependent variable. However, AE confounds VE with algebraic or constant error (CE) (Laabs, 1973; Pepper & Herman, 1970).

Method

Subjects. The *S*s were 24 undergraduates in psychology who took part in the experiment as a course requirement.

Apparatus. A freely moving slide on which *S* placed his index finger was mounted on a straight track. The slide could be moved along the track by either *S* or *E* since a small handle was fixed to the slide on the opposite side to where *S* sat and could be gripped by *E* and used to move the slide with *S*'s arm relaxed. A pointer fixed to the slide moved along a scale so that linear displacements of the slide could be measured. Two freely moving stops were mounted on the track so that position and extent of displacement could be controlled by *E*. A stopwatch was used to time retention intervals.

Procedure. The *S* sat facing *E*, and the different conditions were explained to him. The *S* was then blindfolded. Three movement conditions—voluntary, constrained, and passive—were performed under conditions of 0-sec. delay, 15-sec. rest interval, and 15-sec. task interval. For voluntary movement *S* placed his index finger on the slide, moved it along the track to whatever position he chose, and immediately returned to the initial starting position. The *S*s were instructed to vary the extent of the initial displacement over trials between approximately 10 and 60 cm. Following the retention interval *S* attempted to voluntarily duplicate the initial movement. In the constrained movement conditions, *S* moved the slide to a stop set by *E* and again returned the slide to the initial starting point. During the retention interval *E* removed the stop which indicated terminal position. In the

TABLE 1

Variable, Absolute, and Constant Error (in centimeters) of Movement Duplication in Experiment I

Retention interval	Voluntary			Constrained			Passive		
	VE	AE	CE	VE	AE	CE	VE	AE	CE
0 sec.	1.48	1.81	−.38	3.40	3.15	1.20	2.99	3.39	−2.25
15 sec. rest	1.29	1.65	0.00	4.98	5.20	2.00	4.74	5.90	1.35
15 sec. task	3.93	4.10	3.10	4.53	5.39	2.61	5.27	5.55	−.46

Note. VE = variable error, AE = absolute error, CE = constant error.

passive condition, *S* placed his index finger on the slide and relaxed his arm and *E* then removed the slide to the initial starting point. The *S* always used his preferred arm and initial displacement was always an extensor movement. In all conditions *Ss* were instructed to make both the initial displacement and the attempted duplication as quickly as possible.

Attempted duplication was made either immediately upon returning to the starting point (0-sec. delay) or after 15 sec. The *S* either simply sat with his index finger on the slide for the retention interval until given the instruction "Move" (15-sec. rest), or he was required to count backwards from a 3-digit number spoken by *E* as soon as *S* had returned to the starting point (15-sec. task).

Both movement and interval conditions were within-*Ss* variables counterbalanced in ABCCBA fashion. That is, the order of blocks of movement conditions was voluntary, constrained, passive, passive, constrained, voluntary, and within each block order of retention intervals was 0-sec. delay, rest, task, task, rest, 0-sec. delay, yielding 36 cells each of 6 trials (216 trials overall). To insure approximately equal distributions of initial displacements across conditions, settings in the constrained and passive conditions followed initial settings for each *S* of the settings he had made in the corresponding cell of the first block of voluntary trials. For example, initial displacements made during the second presentation of 6 trials in the 15-sec. rest condition in the first block of voluntary trials were used as standards for duplication in the second presentation of 15-sec. rest in both blocks of constrained and passive movement trials.

Results and Discussion

There were no significant sequence effects and mean VE, AE, and CE for each condition are given in Table 1. A 3 × 3 analysis of variance (ANOVA) of VE with both main effects as within-*Ss* variables showed highly significant effects for movement conditions, $F\ (2, 46) = 157.56$, $p < .000001$, and interval conditions, $F\ (2, 46) = 80.32$, $p < .000001$, and a highly significant interaction term, $F\ (4, 92) = 14.52$, $p < .000001$. Duncan's multiple range test indicated a significant difference ($p < .01$) between the voluntary condition and the other 2 movement conditions with 0-sec. delay. At this interval passive and constrained movement did not differ, thus confirming previous findings (Jones, 1972) in terms of VE. There was no significant difference in either the constrained or the passive condition between rest and task intervals. In the voluntary condition, on the other hand, only the interpolated task produced significant forgetting ($p < .01$), so that the pattern of results for voluntary movement compares with Posner's (1967) findings for visually guided movements.

Figure 1 is a plot of VE against initial displacement. The *S*'s initial displacements were grouped to the nearest 5 mm. and averaged. Inspection of the figure shows no evidence of any tendency for error to vary with extent of movement. Since, however, there was an unequal number of observations for each point on the graph, no statistical check has been attempted.

Following Posner's (1967) criteria it is clear that retention and duplication of voluntary movement may depend upon central processing, since there was no forgetting of voluntary movements over the rest interval while the attention-demanding task interfered with retention.

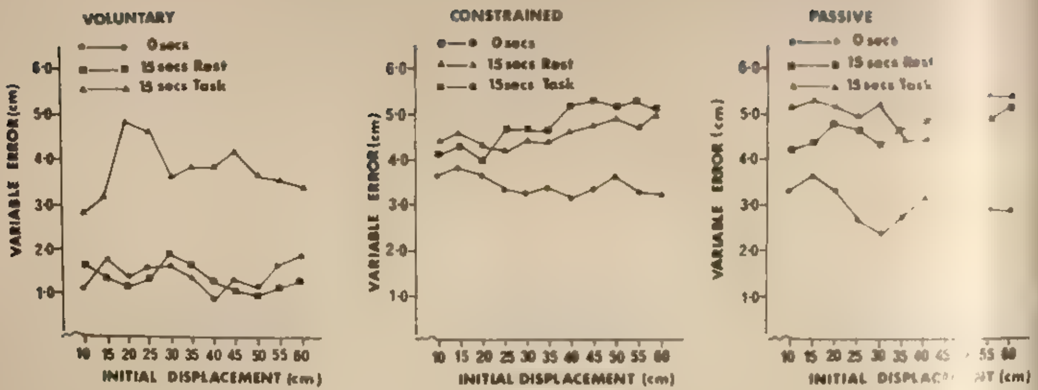

FIGURE 1. Plot of variable error against initial displacement (Experiment 1).

In the constrained and passive conditions, on the other hand, forgetting occurred over time and there was no interference effect. Since only the voluntary condition allowed *S* to preset the initial movement, the present experiment provides evidence that CME rather than joint PFB is a necessary condition for motor rehearsal. Keele and Ells (in press) have recently shown that passive movements may show little forgetting in the absence of distraction, indicating that efferent consistency may not be required for motor rehearsal. However, they carried out passive movement at a constant and steady rate, which may have been highly susceptible to a counting strategy (Laabs, 1973, has shown that counting is a very efficient way of reducing VE in movement duplication), unlike the fast rate of movement used in the present experiment. Consequently, performance in the Keele and Ells study may not have depended upon joint PFB.

Against the present position it might be argued that when *S*s are asked to make a voluntary movement they decide on a stopping position and later remember that position rather than efference from the movement. The second experiment was designed to test such a possibility.

EXPERIMENT II

Method

Subjects. The *S*s were 15 students who had not taken part in Experiment I.

Apparatus and procedure. The apparatus was that used in Experiment I. The *S*s carried out voluntary movement duplication under 2 conditions. The first (constant start) followed exactly the voluntary movement procedure in the first experiment. The second (variable start) was the same as the first except that the starting position of the standard movement and of the attempted duplication were randomly varied on each trial over 6 randomly chosen positions. The second, third, fourth, fifth, and sixth positions were, respectively, extensions of 9, 13, 25, 32, and 45 cm. from the first position, the midline of *S*'s body. Consequently, *S* had to duplicate the extent of the initial displacement, and without the possibility of location cues.

Both movement conditions and interval conditions were within-*S*s variables counterbalanced as in Experiment I. Each *S* received 240 trials overall in blocks of 10 each.

Results and Discussion

Table 2 gives mean VE and mean CE for the various conditions. Analysis of variance of VEs showed that only the intervals factor was significant, $F\ (2, 28) = 362.34$, $p < .000001$. Significance was not obtained for either the movements main effect, $F\ (1, 14) = .01$, or the Movements $\times$ Intervals interaction, $F\ (2, 28) = 1.40$. Duncan's multiple range test showed that differences between the 0-sec. and 15-sec. tasks were significant ($p < .01$) for both variable and constant start conditions, although for neither was there a significant difference between 0-sec. and 15-sec. rest. Experiment II consequently provides evidence that MSTM for blind voluntary movements follows the pattern of retention of visually guided movements (Posner, 1967) even when location cues are eliminated.

TABLE 2

Variable Error (in centimeters) and Constant Error (in centimeters) of Movement Duplication in Experiment II

Retention interval	Constant start VE	Constant start CE	Variable start VE	Variable start CE
0 sec.	1.34	−.51	1.43	−.44
15-sec. rest	1.36	−.47	1.55	−.60
15-sec. task	4.46	2.79	4.14	3.73

Note. VE = variable error, CE = constant error.

Experiment III

In general the results of Experiments I and II are good evidence that CME is a necessary condition for rehearsal in MSTM processes. So far the evidence does not show whether CME is both necessary and sufficient. In bilaterally deafferented monkeys CME certainly seems to be sufficient for motor learning (Taub & Berman, 1968), but in intact human *Ss* it may be that PFB "stamps in" the efferent copy. The present experiment was designed to test the hypothesis that PFB facilitates voluntary movement duplication since, if this is the case, CME would be a necessary but not a necessary and sufficient condition for retention of a voluntary movement over time. By having *S* move the slide against varying degrees of tension, PFB was manipulated. Such a recourse has frequently been held to increase PFB (e.g., Bahrick, 1957) and, since Pepper and Herman (1970) have reported that MSTM for force is analogous to MSTM for extent and position, it is reasonable to expect that increasing force information could lower VE of voluntary movement duplication, given that PFB interacts with CME to stabilize memory for extent of movement.

Method

Subjects. The *Ss* were 15 undergraduates who had not taken part in either Experiment I or Experiment II.

Apparatus. The apparatus was the slide and track system used previously, with the addition that a weight could be attached to the slide by a cord and pulley 10 cm. in diameter mounted at one end of the track.

Procedure. The general procedure followed that already described for the variable start condition in Experiment II, with differential weight on the slide of 0, .5, 1.0, and 1.5 kg. Weight was a within-*Ss* variable counterbalanced across trials as were retention intervals. Each *S* received 240 trials in all.

Results and Discussion

Table 3 gives mean VE and mean CE for each condition. A 4 × 3 ANOVA of VEs with weights and intervals as within-*Ss* factors showed, as for Experiment II, that only the main effect of intervals was significant, $F\ (2, 28) = 329.27$, $p < .000001$. Neither the effect of differential weighting, $F\ (3, 42) = 1.77$, nor the Weights × Intervals interaction, $F\ (6, 84) = .42$, reached significance.

Breakdown of the analysis of variance by Duncan's test did not indicate significant differences between movement conditions at any of the interval levels. Thus the present findings for voluntary movements parallel those of Stelmach (1968) for con-

TABLE 3

Variable Error (in centimeters) and Constant Error (in centimeters) of Movement Duplication in Experiment III

Retention interval	0 kg. VE	0 kg. CE	.5 kg. VE	.5 kg. CE	1 kg. VE	1 kg. CE	1.5 kg. VE	1.5 kg. CE
0 sec	1.57	0.00	1.46	−.74	1.35	−.55	1.37	−.50
15-sec. rest	1.54	.17	1.49	−.36	1.45	−.68	1.37	−.37
15-sec. task	4.21	2.68	4.33	3.47	3.99	2.74	4.17	2.58

Note. VE = variable error, CE = constant error.

strained movements in that augmenting PFB without also giving visual or verbal knowledge of results has little effect on accuracy of movement duplication. Consequently, there is evidence for the hypothesis that CME is both a necessary and sufficient condition for rehearsal in MSTM. Limiting factors on the present conclusion are that force and extent of movement may be subserved by different neural mechanisms despite Pepper and Herman's (1970) findings, and also that VE in the 0-kg. condition may represent the limits of accuracy at present levels of practice so that augmenting PFB could not facilitate motor retention. Further experimentation could study the effects of various tension levels of more long-term practice on blindfolded voluntary movement duplication, since it may be that augmented PFB results in rather faster lowering of VE over a longer time span.

General Discussion

The present results are good evidence that CME is a necessary condition for rehearsal in MSTM, and they also provide a suggestion that CME is necessary and sufficient. Most if not all previous studies of MSTM have failed to consider the CME hypothesis since they have compared the duplication of constrained movements under various conditions. Peripheral feedback theories of MSTM have therefore been given a generality on the basis of insufficient evidence. This is not to say that memory storage capacity for proprioceptive inputs does not exist. It is simply that MSTM for proprioceptive inputs need not involve central mechanisms since storage may be via "preperceptual" kinesthetic afterimages comparable to the sensory afterimages found in vision and hearing, although probably with a relatively longer decay function. It is largely meaningless to speak of interference here; any new inputs to the preperceptual store would erase existing afterimages rather than interacting in classical interference fashion. It is conceivable that voluntary movement also results in an afterimage which may or may not be read in. The absence of any proprioceptive facilitation effect on duplication of voluntary movement would suggest that, if it occurs, preperceptual storage of data from proprioceptors resulting from voluntary movement has little functional utility. The adaptation theory developed by Pepper and Herman (1970) and extended by Laabs (1973) seems to give a good fit to the data on short-term retention of constrained movements. However, such a model may have little extension to the wider field of skilled performance. Ordinarily skill means a pattern of correctly timed *voluntary* movements, and the present data show that voluntary and constrained movements differ in important ways. In skilled performance, generally, the initial learning stages may depend upon visual (or other exteroceptive) feedback matched against the motor memory or efference copy to specify error of movement. With increasing practice *S*s may come to depend solely on CME, contrary to the widely held theory (e.g., Bahrick, 1957) that PFB control replaces visual timing of movements.

The neural basis of CME possibly depends upon cerebello-cerebral relationships. It is known that coordinated movements are disrupted by cerebellar damage even though the motor cortex remains intact. Ruch (1951) speculates that preprogramming of movements would be possible if the motor cortex initially discharges into a circular pathway involving the cerebellum, so that impulses would be stored to be discharged after a fixed delay. Such a "reverberatory circuit" could conceivably mediate memory for voluntary movements over the 15-sec. rest interval in the present experiment.

INFORMATION AMPLIFIED:

MEMORY FOR COUNTERFACTUAL CONDITIONALS[1]

SAMUEL FILLENBAUM[2]

University of North Carolina at Chapel Hill

People remember not only information explicitly specified but also information that can be inferred from that provided directly. It was found, in a recognition memory task that compared to control items *S*s "recognized" the negated antecedent and consequent propositions of previously encountered counterfactual conditionals significantly more often, the latter effect being distinctly stronger. A similar result was obtained for causals related to previously encountered counterfactual conditionals and counterfactual conditionals related to previously encountered causals, the latter being the stronger effect. These results were evaluated in the context of the observation that a counterfactual conditional presupposes (*a*) the negation of its antecedent proposition, strongly suggests (*b*) the negation of its consequent proposition, and (*c*) is intimately related to a causal in which *a* and *b* are conjoined, with *a* taken as the grounds for *b*.

Characteristically, people remember neither the particular surface syntactic form of the sentences they have encountered nor even their deep structure, but rather remember semantic information or propositional content that includes not only information explicitly specified but also information that can be inferred from that provided directly (for a survey of relevant evidence see Fillenbaum, 1973). Thus, Tieman (1971), for example, has shown that if a sentence pair such as *John is tall John is shorter than Bill* is presented, *S*s may later often falsely recognize *Bill is tall*, which can be inferred from the actually presented sentences. Bransford, Barclay, and Franks (1972) provide related evidence in studies concerned with both memory for inferences that may be drawn from sets of semantically related sentences and recognition memory for information inferable from single sentences, given the proper understanding of lexical items such as [illegible] proposition.

These examples represent relatively simple cases of information compounding or the drawing of simple 1-step inferences. There is very little knowledge of what may happen when more subtle types of inferences are involved, even for the case of single sentences, as regards the recall of what is either presupposed or possibly entailed by a sentence, as compared to recall for what is explicitly asserted in it. The research presented herein is addressed to these questions. Recently, linguists have become very interested in presuppositional analysis (see, e.g., Fillmore & Langendoen, 1971). Psychologists have begun to consider how to differentiate between the knowledge involved in what is explicitly asserted and what is presupposed in an expression and to examine the role of knowledge involved in such presuppositions (see, e.g., Miller, 1969; Osgood, 1971). If in processing information one is responsive to not only what is explicitly and directly provided but also to what can or must be assumed if the directly provided information is to be coherent, then a concern with the functions of the presuppositional knowledge becomes inescapable. Particularly intriguing questions arise with regard to possibilities of information gain or amplification in memory, as opposed to the more usual

emphasis on abstraction and information loss.

The conceptual status and proper analysis of counterfactual conditionals have long concerned and perplexed philosophers; nevertheless counterfactual conditionals may provide us with test material that is particularly useful and relevant for the study of memory for information implicit in sentences. A counterfactual conditional presupposes the negation of the antecedent proposition and, while there is some dispute as to whether or not it also entails negation of the consequent proposition, it would seem that it (at the least) strongly suggests such negation and "invites" this as an inference (see Karttunen, 1971). Thus, given *If he had caught the plane he would have arrived on time*, it is presupposed that *He did not catch the plane*, and in most contexts it is at least strongly suggested that *He did not arrive on time*. A counterfactual conditional may also be seen as related to a causal in which the negation of the antecedent is given as the reason for the negation of the consequent, in our example *Because he did not catch the plane he did not arrive on time* or, more stylistically common, *He did not arrive on time because he did not catch the plane*.

Given prior presentation of a counterfactual conditional, one may ask if *S* will later falsely recognize (*a*) the negation of the antecedent proposition, which is presupposed or (*b*) the negation of the consequent proposition, which is strongly suggested if not entailed; and whether false recognition is more frequent for *a* or *b*. Further, given a counterfactual conditional, one may ask if *S* will later falsely recognize its causal relative, which consists of the causal conjunction of *a* and *b*, with *a* given as the reason for *b*. This relation between counterfactual conditional and causal may be viewed as going in the other direction as well (i.e., from causal to counterfactual), since there would appear to be few, if any, occasions appropriate for the causal (*He did not arrive on time because he did not catch the plane*) which would not also assume the counterfactual (*If he had caught the plane he would have arrived on time*). Naturally, we shall be interested in comparing the frequency of recognition errors in the 2 directions. Two experiments in recognition memory are presented herein, the first of which is concerned with memory for the simple offspring of counterfactual conditionals and the second with memory for related complex sentences where the original sentences are either counterfactuals or causals and the recognition sentences include their causal and counterfactual relatives.

METHOD

The basic format of the 2 experiments was the [illegible] were told that they would [illegible] were requested to listen carefully, since they would later be [illegible] After the [illegible] series was finished, they were told that they would hear another series of sentences and would then have to decide whether each sentence was *old* (one they had actually heard before) or *new* (one that had not appeared in the first series). The sentences were presented at a 5-sec. rate both in the initial series and in the later recognition series. The *S*s were run in groups ranging in size from 4 or 5 to 20 or so. There were 110 *S*s in Experiment I and 92 *S*s in Experiment II, all undergraduates fulfilling course requirements.

Design.—Experiment I. Both the original and the test series consisted of a mixture of counterfactual conditionals and simple propositions. Whether [illegible] the original or in the test series, all counterfact[illegible] were positive in both of their clauses with the *if* clause always coming first, as in *If he had caught the plane he would have arrived on time*, and all [illegible] *He did not catch the plane*. Some physical or social [illegible] counterfactuals, as in *If he had eaten the fish he* [illegible] *the boss he would have got a raise*. Matters were arranged so that there were (*a*) conditionals appearing both in the original and the test [illegible] (6 items), (*b*) simple propositions appea[illegible] the original and the test series (8 items), [illegible]ditionals appearing only in the test series (12 [illegible]) (*d*) simple propositions appearing only in the test series (8 items), (*e*) conditionals appearing in t[illegible] original series whose negated antecedent appeare[illegible] [illegible] sequent appeared in the test series (8 items), and [illegible] pearing both at the start and end of the [illegible] series and at the start of the test series, as well as scattered through the original series, so as to make the proportions of conditionals and simple

propositions comparable in the original and test series. Each item appeared twice in the original series; after every item had occurred once, the items appeared again in a scrambled order.

Design—Experiment II. The original series consisted of a mixture of counterfactual conditionals, simple conditionals, and causals involving negation in both of their propositions. Simple conditionals were included as a control so as to be able to determine whether any systematic recognition effects obtained were simply topic effects, i.e., were due to the prior occurrence of the same or similar content. The same type of sentence content used in Experiment I appeared in this experiment. In the causals, the *because* clause always came second, as in *He didn't pass the test because he didn't study.* The simple conditionals involved the same kinds of connections between their clauses as did the counterfactuals, e.g., *If he is treated immediately he will survive* or *If the watches the show he will be bored.* Matters were arranged so that there were (*a*) counterfactual conditionals, simple conditionals, and causals appearing both in the original and test series (6 items of each kind), (*b*) counterfactual conditionals, simple conditionals, and causals appearing only in the test series (6 items of each kind), (*c*) counterfactual conditionals appearing in the original series whose related causals appeared in the test series (6 items), (*d*) causals appearing in the original series whose related counterfactual conditionals appeared in the test series (6 items), (*e*) simple conditionals appearing in the original series whose corresponding causals appeared in the test series (6 items), and (*f*) some filler items. Again, each item appeared twice in the original series, and after every item had occurred once the items appeared again in a scrambled order.

For each *S*, one may determine the number or proportion of *old* responses for each item class and then make appropriate comparisons across item [illegible]; in addition, one may determine the mean [illegible] of *old* responses taken over *Ss* for each [illegible] class. These figures will constitute our [illegible] data

RESULTS

Consider first the results for Experiment I. *Old* counterfactuals (.88) and [illegible] were recognized as *old* significantly more frequently than [illegible] and *new* simple propositions (.14)[6]; *old* counterfactuals [illegible] simple propositions (.53); and there was no difference in recognition between *new* counterfactuals (.12) and *new* simple propositions (.14). Except for the finding that *old* counterfactuals are recognized better than *old* simple propositions, these results are of no particular interest except to show that the situation is one in which *S*s can distinguish between *old* and *new* items, and thus one where the results for offspring items will be relevant. It is indeed the case that offspring sentences, whether negated antecedent (.25) or negated consequent (.44), were judged *old* significantly less frequently than *old* simple propositions (.53), but more interestingly, it is also the case that these offspring sentences were judged to be *old* sentences significantly more often than the control *new* simple propositions (.14). Finally, if we compare offspring sentences where the consequent is negated with those where the antecedent is negated, we find that the former (.44) are judged *old* significantly more often than the latter (.25).

In Experiment II, *old* counterfactual conditionals (.79), *old* simple conditionals (.84), and *old* causals (.73) are recognized as *old* more than *new* counterfactual conditionals (.05), *new* simple conditionals (.04), and *new* causals (.08), with each of these differences highly significant. While the differences between *old* propositions are significant, with simple conditionals recognized significantly more often than counterfactual conditionals or causals and counterfactual conditionals recognized more often than causals ($p < .05$, sign test), these differences are quite small compared to those between *old* and *new* propositions. The differences between various sorts of *new* propositions are slight and nonsignificant. Related sentences are judged *old* significantly less often than sentences that actually had appeared before, but more interestingly, related sentences are judged *old* significantly more often than their *new* controls. Further, looking in a little more detail, we find that counterfactual conditionals related to previously presented causals are "recognized" significantly more often (.47) than causals related to previously presented

[6] Unless explicitly noted otherwise, all differences described as significant represent $p < .01$ on a [illegible]

counterfactuals (.34), and that the latter are "recognized" significantly more often than causals corresponding to previously presented simple conditionals (.25). As noted above, *old* counterfactual conditionals are recognized more often than *old* causals (.79 vs. .73), so perhaps the difference between counterfactuals related to previously presented causals (.47) and causals related to previously presented counterfactuals (.34) represents only a bias toward recognition of counterfactuals. Thus, one needs to correct recognition rates for related sentences by corresponding rates for *old* sentences in order to determine whether the difference between .47 and .34 is reliably greater than that between .79 and .73. Comparing for each *S* the difference in recognition rate between *old* counterfactuals and *old* causals with that between related counterfactuals and related causals, we find that the latter difference is greater for a significant majority of *Ss* ($p < .05$). Thus, even with this correction taken into account, counterfactual conditionals related to previously presented causals are recognized significantly more often than causals related to previously presented counterfactuals.

Discussion

The basic trends of the results are quite clear in each experiment and consistent over the 2 experiments. While offspring or related sentences are recognized less frequently than *old* sentences, they are recognized more frequently than *new* control sentences. Listeners appear to operate on the information directly provided to them, amplifying and elaborating that information. In considering the results more closely, one important caution needs to be voiced with regard to their interpretation. There is no statistical warrant for generalizing these results beyond the specific samples of linguistic material actually employed. There are obviously very severe problems in defining a population of counterfactual conditionals and in sampling at random from such a population; for a discussion of the "language as fixed effect fallacy" and some suggestions for corrective measures, see Clark (in press).

In might perhaps be argued that the positive findings of Experiment I merely represent some sort of a topic effect, with negated antecedent and consequent propositions falsely recognized because *S* remembers having encountered some similar content in the original series (where these contents were actually embedded in various counterfactual conditionals). This argument would not appear to be too convincing given the findings of Experiment II, where there was significantly more false recognitions of causals related to prior counterfactual conditionals than of causals corresponding to prior simple conditionals. If all that we have is a topic effect, too, there should have been no difference in false recognition of causals, whether the antecedent conditionals were simple or counterfactual. Nor would the topic hypothesis account in any obvious way for the fact that in Experiment I, false recognition of negative consequents was significantly more frequent than that of negative antecedents. Why should this be the case if all that is involved is the recognition of propositions that had occurred earlier in some form? Finally, note that recognition involved the negation of the explicit prior contents, and we know that gist memory is generally good, so that on recall *S* can discriminate rather well between an expression and its negation. Nevertheless, a built-in control against the topic hypothesis may be desirable in future work, and one suggests itself readily. In the recognition series, in addition to sentences which negate the antecedent and consequent propositions of earlier counterfactual conditionals, which we might call "legitimate" offspring, one might also include sentences which assert the antecedent and consequent propositions. These might be called "illegitimate" offspring. On the basis of a topic hypothesis, no difference should be expected in false recognition of the legitimate and illegitimate offspring, or perhaps we might expect even greater recognition of the latter than the former (since the illegitimate offspring do not involve negation of previously encountered materials). In terms of the position argued here, however, one would expect more false recognition of legitimate than of illegitimate offspring sentences.

With regard to the first experiment, we can offer no plausible reason as to why old counterfactual conditionals should have been recognized substantially more often than old simple propositions (.88 vs. .53) except for noting that there were substantially fewer of the former (18) than of the latter (32) in the recognition series, and this may have

resulted in less confusion for the former. A problem more directly related to the concern of the present research is posed by the finding that sentences which negate the consequent of a counterfactual conditional are significantly more frequently recognized than those which negate the antecedent of the counterfactual conditional (.44 vs. .25).[4] Recall that the negation of the antecedent is strictly presupposed by the counterfactual and that one cannot coherently conceive of a counterfactual without assuming that its antecedent proposition is negated, while it has been argued that the negation of the consequent is strongly suggested in most circumstances but does not appear to be required. Thus, a sentence such as *If he had caught the plane, which he did, he would have arrived on time* seems inconsistent, while there is in principle nothing contradictory in saying *If he had caught the plane he would have arrived on time, which he did anyway because he took a fast train.* Hence it would appear that, if anything, the negated antecedent is more strongly implied by the counterfactual conditional than is the negated consequent, and yet our results indicate substantially more false recognition of the latter than of the former. In order to make sense of this finding, consider the circumstances under which one might be most likely to employ a counterfactual conditional. For example, one might most commonly say *If he had caught the plane he would have arrived on time* as an explanation for the fact that he was late, a fact that may be simply expressed by negating the consequent proposition, i.e., saying *He did not arrive on time.* If the fact that is being explained is somehow central or focal to the discourse, then it may be reasonable that a proposition that embodies this fact, i.e., the denied consequent, should be more likely to be inferred and falsely remembered than one that only purports to give a reason for the fact, viz., the subordinate denied antecedent.[5] All this, while perhaps sensible enough, is of course somewhat ad hoc, since one could argue that the subordinate causal, just because it gives an explanation, is the more central proposition. What is needed is some manipulation that might systematically change the focus between the 2 propositions, and a determination of whether such a shift in focus has any systematic effect on recognition errors in a task of the sort used in the present study.

With regard to the second experiment, it is again hard to know why there should be differences in recognition of the various kinds of *old* sentences, but here the differences are certainly not of any great magnitude with figures of .79, .84, and .73 for counterfactual conditionals, simple conditionals, and causals, respectively. The finding that causals corresponding to simple conditionals are recognized more often than *new* causals suggests that in some measure there may indeed obtain a sort of topic effect, such that a sentence involving propositional material encountered earlier may be falsely recognized. However, the finding that causals related to previously encountered counterfactual conditionals are significantly more frequently falsely recognized than causals corresponding to previously encountered simple conditionals indicates that such a topic effect cannot totally explain present results. Perhaps the most interesting result is the finding that both causals related to counterfactual conditionals and counterfactual conditionals related to causals are recognized significantly more often than their controls, with the latter effect the stronger one. But why should the counterfactual relative of a causal be more frequently recognized than the causal relative of a counterfactual? Consider what is assumed or what can be assumed given, respectively, a causal and its related counterfactual conditional, e.g., the sentences (*a*) *He did not arrive on time because he did not catch the plane* and (*b*) *If he had caught the plane he would have arrived on time.* One cannot very easily assert *a* without assuming or taking for granted the correctness or truth of *b*, but it is not clear that the converse necessarily holds. For, as was pointed out earlier, *b* could be true and yet there is no absolute requirement that the person in question must have been late, for (*c*) *If he had*

[4] Actually, recognition memory for offspring sentences was examined both for the case where just 1 offspring of a particular counterfactual conditional was presented in the recognition series (with a negated antecedent provided on half of the occasions and a negated consequent on the other half) and for the case where both the negated antecedent and the negated consequent offspring of a counterfactual were presented. Since it made essentially no difference whether one or both offspring were tested, only the pooled results are presented.

[5] Another possibility, pointed out by a reviewer, is simply that semantic material from the main clause is better remembered than material from the adverbial *if* clause.

caught the plane he would have arrived on time, which he did anyway because he caught a fast train, is certainly a possible elaboration. The point is simply that a counterfactual conditional does not appear to entail the denial of the consequent proposition and thus, insofar as this is the case, does not require its related causal. But this analysis too may appear ad hoc. At least it would be supportive of these suggestions if, given causals and their counterfactual relatives, *S*s were more willing to accept the latter as inferences on the basis of the former than the converse.

Even though our interpretation of some of the details of the results must be quite tentative with regard to within-conditions differences, viz. (*a*) the difference between offspring sentences which negate the antecedent and those which negate the consequent and (*b*) the difference between causals related to counterfactual conditionals and counterfactual conditionals related to causals, it seems clear that there are substantial and consistent between-conditions differences, such that offspring sentences and related sentences are consistently recognized more often than their *new* controls. This occurs with regard to both simple offspring propositions (Experiment I) and complex related propositions involving the causal conjunction of the simple offspring (Experiment II).

Wittingly or unwittingly, *S*s seem to go beyond the givens, using information explicitly provided as a clue to what is implicit or can be assumed given that information. If this is the case, then it is incumbent on us to investigate the processes of inference or natural logic involved in such elaboration of information.

MULTIPLE-EXPOSURE EFFECTS ON RESOLUTIONS OF FOUR BASIC CONFLICT TYPES[1]

BARRY D. SMITH[2]
University of Maryland

LEONARD GEHL
New Jersey College of Medicin

The present study examined the 4 Lewinian conflicts in the context of a negative-start paradigm. The *S*s were given 3 trials of each of the 4 conflicts, interspersed among 60 nonconflict trials. Double approach–avoidance (Type IV) conflict produced less adequate resolutions than avoidance–avoidance (Type III), but the 2 conflicts were similar in response modes employed, slow speed of resolution, and high error rate. In addition, considerably less blocking was found to Type III and IV conflicts than in work performed by Hovland and Sears in 1938. Repeated exposure to conflicts produced increases in speed. Resolution lability took the form of increased use of double and blocking responses and decreased use of single responses across trials and was affected by conflict type and response adequacy. Approach–avoidance conflict showed the greatest overall lability, while interclass shifts were greatest for double approach–avoidance.

Two recent studies of human cognitive–motor conflict (Epstein & Smith, 1967; Smith & Epstein, 1967) analyzed responses to approach–approach (Type I), approach–avoidance (Type II), and avoidance–avoidance (Type III) conflict. These studies modified an experimental paradigm used earlier by other investigators (Hovland & Sears, 1938; Sears & Hovland, 1941) to include a negative-start condition in which *S*s were instructionally forced to leave the starting point in the conflict field immediately at the onset of any conflict or nonconflict trial. Results of the Epstein–Smith and Hovland–Sears studies were quite discrepant on some points. In particular, Hovland and Sears found that blocking (remaining at the starting point after trial onset) was a common response to Type III conflict, while Epstein and Smith, using the negative-start paradigm, found blocking to be quite infrequent.

Although the Epstein–Smith (Epstein & Smith, 1967; Smith & Epstein, 1967) studies did introduce the negative-start paradigm, they limited the examination of conflict responses to the first 3 conflict types, eliminating the double approach–avoidance (Type IV) conflict examined by Hovland and Sears (1938), and to a single presentation of each conflict, with the 3 conflict trials interspersed among nonconflict trials. Hovland and Sears did study the resolution of Type IV conflict, but their results were undoubtedly affected by their failure to use a negative starting point. In addition, comparisons between Type IV and the other 3 types in the Hovland and Sears study are difficult, since they used only 20 preliminary trials with each of the first 3 conflict types and 80 with Type IV. The present study was carried out, in part, to evaluate Type IV conflict effects in comparison with the other conflict types.

Hovland and Sears (1938) also studied the effects of repeated exposure to conflict, but only with regard to Type II conflict. A major purpose of the present study was thus to examine, in the context of the negative-start paradigm, response lability (the tendency to change or shift from one response mode to another with repeated exposure to conflict) for all conflict types.

METHOD

Subjects

A total of 52 Introductory Psychology students (24 male, 28 female) were employed as *S*s. Additional *S*s (7) were run or partially run but had to be dropped due to failure to understand basic

[1] The authors are indebted to Frank Rosillo for his help in running *S*s in the study. Computer time was provided by the Maryland University Computer Science Center.

[2] Requests for reprints should be sent to Barry D. Smith, Department of Psychology, University of Maryland, College Park, Maryland 20742.

instructions (2), overt refusal to follow instructions (1), or equipment failure (4).

pparatus

ne conflict apparatus consisted of a board on ich were mounted 4 lights (one red and one ite light at each of 2 goals), a control panel that rmitted *E* to switch on any light or any 2 or re lights simultaneously, and a Standard electric ier wired to start simultaneously with light onset d to be stopped with the termination of *S*'s ponse. The response field was a simple maze, nsisting of a diamond-shaped section followed by a V-shaped section, with paths terminating at 2 goals. The effect of the maze was such that the first section directed *S*'s vision toward one goal, the second toward the opposite goal, and the third section again toward the first goal. Crossways between the sides of the maze permitted *S* to detour from one side to the other during his response. The actual maze was one presented in an earlier study by Epstein and Smith (1967). The only major difference in the present study was that the outside pathways of the maze were narrowed to 2 mm. to increase error frequency and thus make error a meaningful measure.

Procedure

Each *S* was instructed to approach white lights, which he was told represented a million dollars, and to avoid red lights, representing an atomic bomb, by moving a pencil along the paths of the maze. The starting point was made negative by indicating that it would represent a bomb detonation point whenever any light indicating trial onset came on.

The experimental session consisted of a total of 72 trials, including 3 trials for each conflict type, interspersed among 60 nonconflict (simple approach or avoidance) trials. More specifically, after 14 nonconflict trials, 3 different random sequences of 5 trials each were interspersed among nonconflict trials. Each sequence contained all 4 conflicts and a randomly selected control (nonconflict) trial. All *S*s received the same resulting random schedule of conflict and nonconflict presentations. Type I conflict involved the presentation of the 2 white lights simultaneously, Type II consisted of the red and white lights at the same goal appearing simultaneously, Type III was 2 red lights, and Type IV was all 4 lights. A new copy of the response maze was used for each successive trial.

Results

The results of the study were analyzed in terms of response speed, errors made in responding, mode and adequacy of conflict resolution, and response lability as a function of conflict repetition. All analyses involved all 52 *S*s except where specifically noted.

Response Speed and Error

Effects of conflict type and practice were examined through analyses of the rate at which *S*s traversed the maze in response to a given conflict presentation and the relative frequency of errors made. Analyses of rate involved a speed score, calculated as the ratio of total response time on a given trial to distance traversed. The speed score was calculated for each *S* on each of the 3 presentations of each conflict type and on each of the 3 corresponding random control (nonconflict) trials.

A repeated-measures analysis of variance applied to speed scores on the conflict and control trials, with conflicts and trials as sources of main effect variance, yielded a significant trials main effect, F (2, 56) $= 13.71$, $p < .001$. Speed increased across trials, with mean values of 4.66, 5.18, and 5.43 mm/sec for combined Conflict and Control Trials 1, 2, and 3, respectively. Conflict type was also significant, F (4, 112) $= 30.46$, $p < .001$ (Figure 1). Speed decreased with increasing conflict difficulty except for a slight increase on Type IV. A Scheffé (1959) test indicated that the difference between Type III and Type IV conflicts was not significant, F (4, 112) $= 1.85$, $p > .05$. The difference between Type I conflict and control trials was also clearly nonsignificant.

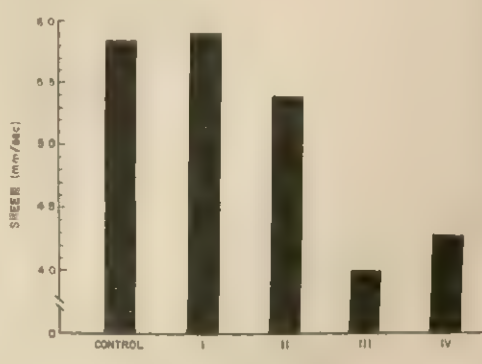

FIGURE 1. Speed of response as a function of conflict type.

A test was planned of the expectation, drawn from the work of Worell (1967), that response speed decreases with repeated exposure to Type IV conflict. The necessary planned comparison was carried out as a Scheffé (1959) test. Means for Trials 1 and 3 on Type IV conflict were 3.83 and 4.71, respectively, representing a significant *increase* in speed rather than the hypothesized decrease, F (8, 224) = 13.51, $p < .10$. A probability of .10 was considered significant due to the highly conservative nature of the Scheffé test.

For the error analyses, an error was defined as any movement of S's response line that crossed the boundary defining a pathway of the response maze. The measure utilized was error rate (errors/speed). The significant effect of conflict type, F (4, 112) = 5.52, $p < .001$, resulted from an increase in error rate across the 4 major conflict types (Figure 2).

Response Mode and Adequacy

Response mode and response adequacy were scored, using the criteria of earlier studies (Epstein & Smith, 1967; Smith & Epstein, 1967). The modes scored were: (*a*) single response, in which the goal is reached directly, without detour; (*b*) double response, in which both goals are reached either by going from one goal to the other or by returning to the starting point and proceeding to the second goal; (*c*) compromise, in which the response terminates at a point intermediate between the starting point and the 2 goals; (*d*) detour, in

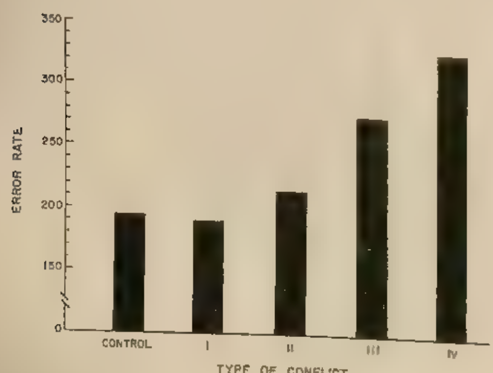

FIGURE 2. Error rate as a function of conflict type.

which the response includes proceeding through one or more crossways of the maze; (*e*) blocking, which is simply a failure to leave the starting point following stimulus onset; and (*f*) disorganized responses, in which no attempt is made to remain within the confines of the maze. Adequacy was scored in relation to specific conflict types. Detour, blocking, and disorganized responses were always scored as inadequate. A compromise response was adequate only for Type III or Type IV conflict, and the double response was adequate only for Type I conflict. Single responses were adequate in Type I conflict, in Type II conflict (to the nonconflicted goal), and on control trials (to the correct goal).

Conflict and corresponding control trials were scored for mode and adequacy, and appropriate percentages were determined. Results of the present study with regard to the first 3 conflict types were in close agreement with the earlier work of Epstein and Smith (1967). Dominant response modes for each conflict type were similar to those in the earlier work, and adequacy decreased with increasing conflict difficulty from Type I through Type III conflict.

Type IV conflict. Since it was not fully investigated in earlier work, the Type IV conflict is of particular interest here. Response mode percentages for Type IV conflict in the present study were quite similar to those for Type III, in most instances. Single (38.5% for Type III and 40.4% for Type IV) and compromise (33.3% and 28.8%) modes predominated for both conflict types, while detour, double, and disorganized responses were infrequent. Blocking was seen in a number of instances in response to both Type III (17.9%) and Type IV (16.6%) conflict. Hovland and Sears' (1938) percentages were quite different, with 72.5% blocking responses and 12.5% double responses to Type IV conflict.

Though resolution modes were similar in the present study, adequacy differentiated Type III and Type IV conflicts. A chi-square analysis of adequacy involved only those 25 Ss who differed in adequacy

from one conflict to the other. The resulting chi-square demonstrated that the Type IV conflict did result in a greater frequency of inadequate responses than did Type III, χ^2 (1) = 9.7, $p < .01$.

Response Lability

Mode lability analyses examined shifts in response mode from Trial 1 to Trial 2 and from Trial 2 to Trial 3 (Table 1). It was found that Type II conflict resulted in the greatest degree of lability, while Type I conflict and control trials showed the least total mode shifts, χ^2 (4) = 26.1, $p < .001$.

Lability data were further examined to determine the extent to which *S*s tended to shift toward or away from each major response mode with increased conflict experience. Summed over conflict types, there were significant differential tendencies to shift away from the single response mode over trials, χ^2 (1) = 4.25, $p < .05$, and toward the adequate double response mode, χ^2 (1) = 7.11, $p < .01$, and the inadequate blocking response, χ^2 (1) = 7.12, $p < .01$.

A further analysis of shift involved grouping the various responses to form the 2 classes originally defined by Hovland and Sears (1938). Class 1 contains responses that generally terminate at a goal, including double, single, and disorganized responses; while Class 2 contains only the blocking and compromise modes, which do not terminate at goals. The number of shifts from Class 1 to Class 2 modes (24) was considerably greater than the number of shifts (8) in the reverse direction, χ^2 (1) = 8.0, $p < .01$; and the number of interclass shifts (23) from Trial 1 to Trial 2 was significantly greater than the number of shifts (9) occurring from Trial 2 to Trial 3, χ^2 (1) = 6.1, $p < .02$. In addition, frequency of interclass shifts increased with increasing conflict difficulty, with the greatest number occurring on Type IV conflict, χ^2(4) = 19.6, $p < .001$.

Two additional factors influencing response lability were suggested by the work of Lewin (1935) and Hovland and Sears (1938). Lewin hypothesized that a single

TABLE 1

Response Lability (% Shifts) as a Function of Conflict Type

Conflict	Response mode shifts	
	Trial 1 to Trial 2	Trial 2 to Trial 3
Type I	15.4	9.6
Type II	48.1	38.5
Type III	32.7	25.0
Type IV	38.5	25.0
Nonconflict	11.5	17.3

Note. All percentages are based on 52 possible shifts (one per *S*) for each conflict type between each 2 trials.

response to a given goal in a Type I conflict situation weakens the valence of the selected goal, resulting in a shift to the opposite goal. This hypothesis was not confirmed in the present study, since only 6.5% of the *S*s shifted goals on either the second or third trial of the approach–approach conflict. An alternative hypothesis is that response lability is more a function of the reaction type or mode itself than of the field situation or conflict type (Hovland & Sears, 1938). This contention was not supported by present results, since the major response modes with which Hovland and Sears were concerned—single, double, and compromise—were associated with the very similar shifting values of 30.3%, 37.3%, and 28.1%, respectively.

A final consideration was the extent to which response lability is a function of the adequacy of the initial response. Response lability between Trials 1 and 3 was greater for inappropriate than for appropriate responses. Specifically, the mean percentage shift across the 6 inappropriate response modes (inappropriate detour, double, compromise, single, disorganized, and blocking responses) was 60.2%, while the mean for appropriate modes (appropriate double, single, and compromise responses) was 16.8%. An exception was the inappropriate blocking response, which was among the most stable responses, with only 20% shifts.

Discussion

Two basic questions studied in the present investigation concerning the Type IV conflict

related to its resolution under conditions of negative start and its relationship to other conflicts, particularly Type III. First, it was apparent that under the negative-start conditions of the present study, Type IV conflict, like Type III, elicited markedly less blocking than occurred in the work of Hovland and Sears (1938). Type III and Type IV conflicts were also similar to each other in relation to further response modes, speed, and error measures, while differing from the other conflicts. Only adequacy differentiated the 2 conflicts, with Type IV producing less adequate responding.

Both the Type III and Type IV conflicts, as well as the remaining 2 conflict types, showed some effects of repeated exposure. The overall increase in speed with practice was accompanied by differential mode lability, which was a function of conflict type and initial response adequacy. The hypotheses of both Lewin (1935), who stated that approach–approach conflict is subject to frequent shifting from goal to goal, and Hovland and Sears (1938), who said that lability is largely a function of initial response mode, had to be rejected on the basis of present results. The failure of the Lewin hypothesis may have been due to the use of left and right goals rather than, for example, forward and reverse goal points, since 93.9% of all single responses on Type I conflict were to the right-hand goal. Thus, right-lateral dominance, coupled with high preexperimental response strength for responses involving movement toward the right, may have affected results. Somewhat more massed practice may also be a necessary condition for the confirmation of the Lewin hypothesis. The negative-start condition of the present study, combined with the use of a maze rather than an open-field situation, and the fact that Hovland and Sears examined lability of only Type II conflict, may have contributed to the discrepant findings in the 2 studies concerning their hypothesis.

Further lability results showed that responses tend to shift away from inadequate early attempts and to shift from goal (Class 1) to nongoal (Class 2) modes, while interclass shifting becomes more frequent, the more difficult the conflict. These findings are related in that it is principally the Type III and Type IV conflicts that elicit inadequate responses, produce the most compromise and blocking (Class 2) responses, and have the highest interclass lability. In e[illegible] early inappropriate responses to Type III and IV conflicts often result in shifts to [illegible]r adequate compromise or inadequate blocking responses, depending on relevant individual difference variables.

The fact that approach–avoidance (Type II) was the most labile conflict when response class was not considered can be explained in relation to the Lewin (1935) and M[illegible] (1944) models. Both of these theories concluded that the response to Type II should reach some compromise point between the starting point and the conflicted goal. Lewin hypothesized, in addition, that *Ss* experienced in responding to approach–avoidance conflict situations may leave the field, a hypothesis consistent with the position that conflict produces a state of increased drive (Brown & Farber, 1951). In the latter case, leaving the field would be seen as one way of reducing the drive resulting from the conflict situation.

Present results for Type II showed single responses to the nonconflicted (51.9%) and conflicted (25%) goals to be most frequent, with compromise (3.2%) and detour (13.5%) modes relatively rare. The instructions and obvious boundaries of the paper maze in the present study made it difficult for *S* to literally leave the field. It was, however, quite possible to leave (detour or compromise) or avoid (single response to nonconflicted goal) the path leading directly to the conflicted goal and hence reduce the drive. Given these response alternatives, the unique ambiguity of the Type II conflict, resulting from the absence of any information (lights) concerning the status of the nonconflicted goal, may well have been responsible for the observed lability of this conflict. Moreover, the predominance of single responses is consistent with the fact that the single mode is the most practiced, due to its use on nonconflict trials.

In conclusion, given a conflict situation in which the starting point is negative and field departure difficult, the present study provided mixed support for several hypotheses drawn from earlier conflict theories and demonstrated that only response adequacy clearly differentiates Type IV conflict from Type III. Lability was shown to be determined primarily by initial response adequacy and conflict type. Further work systematically varying starting-point status, repetition of exposure, difficulty of field departure, situational ambiguity, and

relative goal location should make it possible to suggest some specific modifications of earlier conflict theories.

MODES OF EXTRACTING INFORMATION IN CONCEPT ATTAINMENT AS A FUNCTION OF SELECTION VERSUS RECEPTION PARADIGMS

NEAL S. SMALLEY[1]

State University of New York College at Plattsburgh

Measures of 2 modes of inference were developed: the V measure counts inferences about attributes which are varied from a focus instance, and the C measure counts inferences about constant attributes. In 2 experiments Ss in a selection paradigm were compared with a yoked group in a reception paradigm. Both experiments supported the prediction that the reception group would give more C inferences, but found no difference in V inferences. The results are explained in terms of the selective attention to S's current hypothesis which is produced by the task of selecting, rather than receiving, information. The use of the V and C scores to measure focusing and scanning strategies is discussed.

The purpose of this investigation was to examine 2 methods of extracting information from instances in a concept attainment (CA) task. In particular, it was concerned with whether the method differs when *S* can choose the instances he wishes to examine (selection paradigm), as opposed to a situation where the choice of instances is not in his control (reception paradigm).

Attempts to experimentally compare the selection and reception paradigms (Hunt, 1965; Huttenlocher, 1962; Laughlin, 1972; Lowenkron & Johnson, 1968; Murray & Gregg, 1969; Schwartz, 1966) have based the comparison on effectiveness of performance as measured by number of trials (instances chosen) to criterion or solution time. No consistent pattern of results, favoring either selection or reception conditions, has emerged.

One alternative approach is to focus research attention on the more fundamental processes at each step of the CA task rather than on effectiveness of overall performance. The present investigation focused on the methods employed by *S*s to extract information from each instance encountered, employing measures of 2 such methods which were identified in a previous, unpublished study using the selection paradigm. For each instance which *S* chose he was asked for a reason for his choice and, after he was told whether the card was positive (an exemplar) or negative (a nonexemplar), he was asked for any inference he had drawn on the basis of the instance. The statements which *S*s made were classified into 3 types—V, C, and VC—which are illustrated in Table 1. The V inference is a statement about one or more attributes (or values of those attributes) which are varied from the positive example which *S* is given at the beginning of the trial. The C inference is a statement about one or more attributes (or values) which are constant, or the same as the attributes of the given instance. The VC inference is a statement about both varied and constant attributes. Table 1 gives examples of the 3 inference modes for each of the 4 main types of situations that commonly occur in conjunctive CA tasks. The task given as an example has stimuli with 4 attributes (represented as letters) and 2 values for each attribute (represented as numbers immediately following each letter). The concept shown is a 2-element conjunctive concept, and the inferences given are the logically correct ones for each of the 3 inference types. In addition to minor differences in wording, the inferences actually given by *S*s showed an occasional logical error and were often less complete in the cases where multiple inferences are possible (e.g., Situation I–C).

Employing a measure of mode of infor-

[1] Requests for reprints should be sent to Neal S. Smalley, Department of Psychology, State University College, Plattsburgh, New York 12901.

mation extraction has the additional advantage of overcoming a problem inherent in the design of experiments comparing reception and selection paradigms. In order to equate the groups on stimuli received, previous studies have employed the yoked group design in which each reception *S* received the sequence of instances actually chosen by an *S* in the selection group. However, Lowenkron and Johnson (1968), following Church (1963), have argued that *S*s differ in their ability to solve CA problems and that selection *S*s will choose sequences of instances whose difficulty is appropriate to their abilities. Since reception *S*s are paired with selection *S*s at random, the correlation between ability level and sequence difficulty will not be present in the reception group, and this may result in a negative bias against the reception group.

A study which uses as its dependent variable a measure of information extraction can avoid this bias because differences between *S*s in their abilities to extract information should be minimal. With a 2-element conjunctive concept, the task of drawing an inference from each instance is relatively easy and almost all *S*s should produce a logically correct inference for each instance, as was the case in the exploratory study. Thus *S*s should not differ substantially in their ability to draw inferences but rather in the manner in which they draw them.

The present study compared selection and reception groups, hypothesizing that *S*s in the selection condition would make more V inferences and that *S*s in the reception condition would make more C inferences. Consistent with previous suggestions (Dienes & Jeeves, 1965; Hunt, 1965), the selection condition, which provides the opportunity for manipulation of the type and order of information to be examined, is assumed to thereby permit *S*s to take a more active role, systematically varying the attributes of the stimulus materials and thus focusing their attention on V attributes. On the other hand, the reception condition, since it does not provide this opportunity, is assumed to engender a more passive role in which *S* attends to patterns of relationships common to the instances observed and thus focuses on C attributes.

TABLE 1

THREE INFERENCE TYPES FOR THE FOUR MOST FREQUENT SITUATIONS WITH A TWO-ELEMENT CONJUNCTIVE CONCEPT

Situation type	Instance	Category	Inference mode	Inference
I	A1,B1,C1,D1	+		(The given instance.)
	A2,B1,C1,D1	+	V	A1 is not part of the concept.
			C	(B1 and C1), (B1 and D1), and (C1 and D1) are possible concepts.
			VC	(A1 and B1), (A1 and C1), and (A1 and D1) are not the concept.
II	A2,B1,C1,D1	−	V	A1 is part of the concept.
			C	(B1 and C1), (B1 and D1), and (C1 and D1) are not the concept.
			VC	(A1 and B1), (A1 and C1), and (A1 and D1) are possible concepts.
III	A2,B2,C1,D1	+	V	Neither A1 nor B1 is part of the concept.
			C	(C1 and D1) is the concept.
			VC	(A1 and B1), (A1 and C1), (A1 and D1), (B1 and C1), and (B1 and D1) are not the concept.
IV	A2,B2,C1,D1	−	V	Either A1 or B1 or both are part of the concept.
			C	(C1 and D1) is not the concept.
			VC	(A1 and B1), (A1 and C1), (A1 and D1), (B1 and C1), and (B1 and D1) are possible concepts.

Note. The V inference is a statement about one or more attributes (or values of those attributes) which are varied from the positive example which *S* is given at the beginning of a trial. The C inference is a statement about one or more attributes (or values) which are constant, or the same as the attributes of the given instance. The VC inference is a statement about both varied and constant attributes.

EXPERIMENT I

Method

Subjects and design. The *S*s were 28 college freshmen who volunteered during a summer orientation program prior to their first year of college. Two groups were employed, a reception (REC) and a selection (SEL) group. In order to control the stimuli received by the 2 groups, a yoked group design was used in which *S*s in the REC and SEL groups were randomly paired and each REC *S* received the instances chosen by his paired SEL *S*. Thus *S*s were randomly assigned to groups with the necessary restriction that a particular *S* not be assigned to the REC group unless an unpaired SEL *S* who had already completed the experiment was available.

Materials. The instances were hand-lettered on 5.1 × 7.6 cm. white cards and arranged in an ordered

array. Each instance contained 4 capital letters—A, H, Q, and R—each of which had either the number 1 or the number 2 printed as a subscript below it. The letters were the attributes and the subscripts were the values of those attributes; therefore this was a 4-attribute, 2-value task. The array contained all possible instances ordered so that each card was adjoined on all sides only by cards which varied from it in a single attribute.

Since the purpose of the experiment was to study types of inferences, it was desirable to control possible sources of error and confusion for the *Ss*. Exploratory studies seemed to indicate that unitary stimuli such as the usual geometric figures used in CA experiments occasionally produced such confusion, presumably due to failures to separate the attributes combined in the single geometric figures. The letter-and-subscript form of the stimuli in the present experiment was an attempt to reduce this confusion by physically separating the attribute value pairs.

Procedure. The directions read to *S* explained the construction of the cards, stated that for each problem the concept would involve only 2 attributes conjunctively combined, and gave an example of one such concept. The directions for the 2 groups differed only in whether the *Ss* were instructed to select cards from the array (the SEL group) or were told that *E* would give them the cards (REC group).

All *Ss* received 4 problems, or different concepts, each of which began with the card $A_1H_1Q_1R_1$, which was always positive. For each successive card, 4 steps were followed. First, a SEL *S* chose his card; a REC *S* was given the card chosen by his paired SEL *S*. Second, *Ss* in both groups were asked: "Do you have any hypotheses about what the concept might involve?" Third, the category of the card (positive or negative) was announced, and the card was placed in either of 2 columns headed with a [illegible] "Does that card lead you to any particular conclusions?" In the SEL group a problem was completed when *S* announced the correct concept—unless that announcement was a guess, that is, unless *S* had not chosen enough cards to be logically certain. When such guesses occurred, *S* was encouraged to pick additional cards to "test" his guess. In the REC group a problem was not completed until *S* had received all of the cards which his paired SEL *S* had chosen for that problem, even if the REC *S* attained the concept earlier than the SEL *S*. If a REC *S* had not attained the concept when the SEL *S*'s cards ran out, he was encouraged to go back over the cards and attempt to figure out the concept. He was not given any additional cards. These procedures for the 2 groups insured that each pair of *Ss* would have the opportunity to examine exactly the same cards from which to draw inferences.

The sessions were tape-recorded using a cassette recorder which was in full view of *S*. In addition, *E* wrote down each card that *S* chose or was given and attempted to note every card to which *S* pointed [illegible] his verbal explanations.

These procedures differ from some versions of the CA task in that the cards [illegible] removed from the array and placed in posi[illegible]nd negative colum[illegible] where they remained i[illegible] view during the entire problem. This was done [illegible]imize the effects of differences in memory ab[illegible] and to avoid the confusion which err[illegible] memory for past in[illegible]stances can sometimes pro[illegible]

Results

Each statement [illegible]n answer to the questions was first [illegible]orized as an inference or a nonin[illegible] An inference was defined as a sta[illegible] which included one or more attribu[illegible]e letters A, H, Q, R) or values (a l[illegible]umber combination such as A_1) and [illegible]elated these to the concept in some [illegible]amples of such relationships are st[illegible] that the attributes or values a[illegible]ot, or possibly [illegible] the concept [illegible] Only inferences we[illegible] further.

Each inference [illegible]ced in one of [illegible] categories: V, C, or VC. An inference was placed in the V categ[illegible]ll the attributes or attribute–value [illegible] mentioned were ones which were different from, or varied from, the given card. Since the given card was always $A_1H_1Q_1R_1$, the V inferences were always about attributes which had a subscript of "2" on the card being discussed. An inference was put in the C category if all the attributes or attribute-value pairs mentioned were the same as, or constant with, the given card. Thus C inferences were always about attributes which had a subscript of "1" on the card in question. Finally, an inference was classed as VC if the attributes or attribute-value pairs mentioned in the inference included at least one which was V type and one which was C type, as just defined. Examples of each type of inference in the situations most common for this task are given in Table 1. In cases such as the statement for Situation 1, each of the possible concepts which *S* actually gave was counted as a separate C inference.

There were, then, 3 response measures: the total number of V, of C, and of VC responses over the 4 problems. The SEL and REC groups were compared on each of these 3 measures by means of a matched

groups *t* test. The mean number of C inferences in the REC group was 24.6, and in the SEL group it was 14.9. The difference was in the predicted direction and was statistically significant, t (13) = 3.15, $p < .01$. The V means 10.8 (SEL) and 8.9 (REC) were in the predicted direction but were not significant, t (13) = .68. No prediction was made about the VC measure, nor was it found to significantly distinguish the 2 groups, t (13) = 1.40.

Thus the results were consistent with the hypothesis that the reception paradigm tends to produce a more passive, pattern-oriented approach to extracting information from instances than does the selection approach. However, there was no support for the hypothesis that the selection paradigm produces a more active, systematic approach to information extraction.

For comparison with previous studies employing measures of effectiveness of performance, the number of trials (instances) required to attain each of the 4 concepts was computed. A concept was said to be attained on the first trial in which (a) S announced the correct concept without mentioning any alternative concepts, and (b) it was logically possible to definitively conclude what the concept was. Using this criterion, the mean number of trials required to solve all 4 problems was 16.7 in the REC group and 17.4 in the SEL group, a difference which was statistically significant, t (13) = 2.86, $p < .02$. The superior performance of the REC group obviously contradicts the possibility of a negative bias against the reception group resulting from the yoked control design. Additional evidence against this bias was also furnished by the error rates, which failed to suggest a difference in difficulty between the stimulus sequences for the 2 groups. There were no differences in either the total percentage of logically erroneous inferences (5.2% for SEL and 4.8% for REC) or in errors in particular types of inferences: for V inferences, 6.0% (SEL) and 4.0% (REC), and for C inferences, 3.4% (SEL) and 4.6% (REC).

One possible objection to Experiment I centers on the part of the procedure that asked *S* to give any hypotheses he held about the concept. In answering this question, which was asked just after he had made his choice of an instance, the SEL *S* may have given the hypothesis he was attempting to test with that choice, rather than giving all the possible hypotheses which might be tested with that instance. The REC *Ss*, unrestricted by a prior hypothesis, may have been able to give more complete lists of possible hypotheses. Since the hypotheses were combined with the inferences given in response to the question asking for *S*'s conclusions, it is possible that the observed differences were due primarily to the difference between the number of hypotheses given. However, a repetition of the t tests based only on the inferences given to the "conclusions" question produced findings nearly identical to those obtained initially: for the C measure, t (13) = 3.90, $p < .001$; for V, t (13) = .92, *ns*; and for VC, t (13) = 1.45, *ns*.

This revision in the C measure does not, however, entirely meet the objection. The "hypotheses" question itself may have directed the REC *Ss* to look for possible hypotheses which they would not otherwise have produced. Therefore, asking for hypotheses may have facilitated the performance of REC *Ss* while giving no corresponding help to SEL *Ss*, who were presumably set by the hypothesis they had already produced in the process of selecting an instance. To eliminate this interpretation of the results, a second experiment was run which replicated the first one except that the request for hypotheses was omitted from the procedure.

Experiment II

[illegible] tion and a yoked reception group.

Procedure. All aspects of the procedure [illegible] student who was the [illegible]

the concept might involve?" was omitted from the procedures for both groups. Thus the only opportunity to make verbal inferences was in response to the question asking for conclusions from each card.

Results

The 3 measures were derived in exactly the same way as in Experiment I. Again, there was a considerable difference between the mean number of C inferences in the REC group (24.6) and the SEL group (17.8), a difference which was statistically significant, t (15) = 3.51, $p < .01$. For the V measure, neither the direction nor the magnitude was as predicted—mean SEL = 5.6, mean REC = 6.8, t (15) = .62. Again, the VC measure did not produce a significant difference, t (15) = .62. In this experiment, there was no significant difference in trials to criterion—means of 19.6 (SEL) and 19.9 (REC), t (15) = .50—providing less strong but still consistent evidence contrary to the hypothesis of negative bias against the REC group. As in Experiment I, no significant differences in error rates were found. For the SEL and REC groups respectively, the percentages of erroneous inferences were 4.3% and 7.2% for all inferences combined, 3.3% and 3.7% for V inferences, and 3.9% and 8.4% for C inferences.

The C score may be seen not only as a measure of a mode of drawing inferences but also as a measure of the completeness with which these inferences are drawn. Recall that in Situations I and II, 1, 2, or all 3 possible concepts may be given. Each concept given was counted into the total C score. Thus, the more such concepts S gave for each instance, the more complete was the inference process and the greater was the information extracted from the instance. However, we may ask whether the difference in C scores simply reflects greater completeness in the REC condition than in the SEL condition, or whether there is an actual preference in the REC condition for inferences of the C type. To get some indication of this from the present data, the C score was revised by counting only one C inference per instance in cases where 2 or 3 such inferences were given; the mean C scores for the REC and SEL groups then became 17.5 and 15.2, respectively. The difference is in the predicted direction, although not significant, t (15) = 2.01.

Discussion

The major difference between the selection and reception conditions appears to be in the completeness of the C inferences drawn by Ss in the selection condition. Thus, instead of the hypothesis of active and passive roles initially suggested, a better formulation can now be offered. The task of selecting instances may set S to extract only information relevant to his current hypothesis and may therefore result in his ignoring additional information which the instances contain. When S receives rather than selects instances, he may be less set by any hypotheses he has and therefore able to extract more information from each instance.

More generally, the modes of information extraction identified in this study appear to underlie the CA strategies described by Bruner, Goodnow, and Austin (1956). In *focusing* strategies, S selects an instance which varies one or more attributes from the given instance. His goal is to gain information about those attributes, and so his inferences should be about varied (V) attributes. In *scanning* strategies, S tests one or more possible concepts which are directly represented in the test instance. Since these possible concepts will also be embodied on the given card, the inferences drawn will be about constant (C) attributes. However, the V and C scores are not perfect indexes of the strategies employed because Ss' verbal statements include additional deductions about attributes and concepts not directly tested by a particular card. The V and C scoring system compares favorably with the measure of focusing developed by Laughlin (1965) in that it requires fewer, simpler decisions by the scorer and is applicable to both reception and selection paradigms.

Perhaps because the V and C measures reflect modes of extracting information from instances rather than either patterns of instance selection or effectiveness of performance, they may prove applicable to a variety of experimental situations and problems.

EFFECT OF NOISE ON THE STROOP TEST

L. R. HARTLEY[1] AND R. G. ADAMS

Medical Research Council, Applied Psychology Unit, Cambridge, England

Noninterference tests and 2 versions of the Stroop color interference test were used to test *S*s in loud noise and quiet. Interference and noninterference tests were performed during the first and last 10 min. of a 30-min. exposure to noise and quiet. Interference in noise and quiet was measured by taking the difference between performance on interference and noninterference tests. The *S*s in Experiment I who were tested at both exposure durations showed increased interference in noise. In Experiment II, exposure duration and practice were assessed independently. The brief exposure to noise was beneficial and decreased interference, and the long exposure increased interference, suggesting a cumulative adverse effect of noise.

Exposure to loud noise undoubtedly produces changes in human performance efficiency (Broadbent, 1953). These performance changes have been attributed to the amount of stimulation being received: excessive stimulation from intense noise is supposed to overarouse *S* and cause impairment (Broadbent, 1963), but a moderate amount of stimulation can cause some improvement (Davies & Hockey, 1966; McGrath, 1963). These performance changes have occurred toward the end of a lengthy (30-min.) test in continuous loud noise (Broadbent & Gregory, 1963). The changes occurring with continued exposure to loud noise include increases in errors and pauses in a serial reaction task (Wilkinson, 1963) and increased attention to high-probability sources of information (Hockey, 1970). Broadbent (1971) suggests that one interpretation of these results is that the increased arousal accompanying exposure to intense noise leads to an impairment of the mechanism that filters information from the environment for further processing. Some of the evidence for this view derives from a series of studies involving the visual identification of common and uncommon words in noise. It was found that the uncommon word was more difficult to see in noise, but only when both classes of words were present. Noise did not alter the ratio of misperceptions of common and uncom[illegible] words. Noise clearly affected the [illegible] tion of the stimulus rather than cha[illegible] the bias in responding to one or the [illegible] class of words.

In the Stroop test (Jensen & Roh[illegible] 1966; Stroop, 1935) color names written in inks of different hues, excluding ink of the hue the name indicates, are presented to *S*s, who are required to name the hue of the ink and not the color name. The comparison or control task may involve naming monochromatic color names or naming the hue of the ink in which nonverbal symbols are written. Responding to the hue of color names takes longer than either of the comparison tasks because both name and hue are appropriate to the same set of responses. Hence, the irrelevant feature of the stimulus (color name) must be excluded from the analysis. The color name dimension must be filtered from the hue dimension (Dyer, 1971).

It would be expected that if filtering is affected by noise-induced arousal, the Stroop test should show impairment in noise which would increase with length of exposure to noise, as other tests have shown it does. In the following experiments, versions of the test not requiring an overt verbal response were used.

Experiment I

Method

Subjects. Eighteen enlisted men served as *S*s, and each *S* was tested individually. No *S* had

---

[1] Requests for reprints should be sent to L. R. Hartley, Medical Research Council, Applied Psychology Unit, 15 Chaucer Road, Cambridge, England.

done the test before. All *S*s had normal hearing; less than 35-db. loss in one ear or 30-db. loss in both ears at any of 7 test frequencies covering the audible range.

Materials. Two packs of 100 cards, one experimental (E) and the other control (C), were used. Cards in the E pack displayed 5 color names red, blue, green, violet, and black—written in uppercase lettering in inks of the 5 hues. No color name was ever written in the hue the name indicated. There were 5 cards of each hue/name combination in the pack. Each card in the C pack displayed 5 crosses drawn in any one of the 5 hues of the E pack. There were 20 cards of each hue in the pack. The *S*s sorted each of the 2 packs as quickly and accurately as possible into 5 piles corresponding to each of the hues.

Procedure. All 18 *S*s were tested in conditions of noise (N) and quiet (Q). These 2 tests were given on separate days at between 8:00 and 9:00 A.M. Each *S* sorted both the E and C packs in the first and last 10 min. of a 30-min. exposure to N and Q. The *S*s read magazines in the interval between the tests at the beginning and end of the exposure.

Broad-band noise was used in all conditions, having constant energy per cycle between 50 and 4,000 Hz. In N, this was presented at 100 db., and in Q, at 70 db., measured on the C scale, having a substantially flat frequency response.

Half of the *S*s had the N condition on their first test and half had the Q condition. Presentation order of the E and C packs to each group of 9 *S*s was counterbalanced within each *S*. Prior to the first test, *S*s practiced sorting both packs of cards in Q. Each *S* was told his scores after sorting each pack, and the scores were also displayed on a group chart near *S*.

TABLE 1

MEAN TIME (IN MIN.) TO SORT EACH CARD PACK UNDER EACH CONDITION

Time of sorting task	Card-pack stimuli	
	Color names	Crosses
Quiet condition		
First 10 min.	2.6156	2.3167
Last 10 min.	2.2630	2.0722
Noise condition		
First 10 min.	2.6990	2.2593
Last 10 min.	2.3880	2.0620

Note. Time of sorting task refers to its occurrence within the 30-min. exposure to either quiet or noise.

Results

The times taken to sort each pack were analyzed using a repeated measures analysis of variance with logarithmic transformation of the scores to achieve normality of distribution. Interactions of each factor with *S*s were used as error terms.

Sorting on the second test, following the 20 min. of prior exposure, was faster than sorting on the first test in every condition ($p < .008$). Pooling tests in the N and Q conditions, the type of pack sorted interacted with the position of the test in the $\frac{1}{2}$-hr. exposure, $F\ (1, 17) = 6.32$, $p < .025$. The difference in time taken to sort names and crosses was less at the end of the exposure than at the beginning. Comparing tests in the N and Q conditions independently, N increased the time taken to sort the E pack by about 3% and decreased the time taken to sort the C pack by about 1% (Table 1).

The difference in time taken to sort E and C packs was nearly twice as large in N (22.97 sec.) as in Q (14.69 sec.), $F\ (1, 17) = 4.55$, $p < .05$. Although noise caused an increase in the difference in sorting time of the 2 packs, there was no evidence that it interacted with the position of the test in the $\frac{1}{2}$-hr. exposure ($p = .25$). The increased difference in sorting time of the 2 packs can therefore be regarded as similar at the beginning and at the end of $\frac{1}{2}$ hr. of noise.

EXPERIMENT II

Experiment I examined whether noise increased the interference of color name with the selection by hue and whether this interference increased with the duration of noise exposure. The fact that there was no increased interference with a long as compared to a short exposure to noise could be due to a number of factors; in particular, the fact that duration of exposure to noise was confounded with practice at test, and the latter reduced the interference. In Experiment II, these 2 variables are assessed independently and a modified version of the test, involving a much smaller motor component, was used.

Method

Subjects. Two groups of 16 *S*s each were tested. All were enlisted men, none of whom had taken part in Experiment I. The *S*s were tested in groups of up to 6 at a time. All *S*s had normal hearing; less than 35-db. loss in one or 30-db. loss in both ears at any of 7 test frequencies covering the audible range.

Materials. In the modified version of the Stroop test, the material was presented in a written form, and *S* ticked the appropriate item, rather than sorting it from a set of cards. The material was presented in a series of sheets, each containing 32 lines of material. On E sheets, each line was made up of the color names, red, green, brown, black, and blue, written in inks of these hues. No color name was written in the hue that the name indicated. Each line on the sheets contained 1 stimulus color name on the left and the 5 possible response color names on the right. Each *S* was instructed to select from the response set the color name appropriate to the hue of the stimulus name. As a control, a noninterference (C) test was also used. The format of these C sheets was identical to that of the E sheets, and they contained the same set and number of color names as the E sheets; however, color names were all printed in black ink. Each *S* was instructed to select from the response set the same color name as the stimulus color name.[2] In both C and E tests, *S* crossed out the response word in as many lines of material as he could in 5 min.

Procedure. All *S*s were tested twice, once in both the N and Q conditions. A practice test was also given. These 3 tests took place on 3 consecutive days between 8:00 and 9:15 A.M.

Broad-band noise having equal energy per octave was used in all conditions. This noise was presented at 95 db. in the N condition and at 70 db. in the Q condition, measured on the C scale. The differences in sound-pressure level and spectrum of the noise between the 2 experiments reported here were necessitated by administrative reasons outside *E*'s control.

One group of 16 *S*s (Group 1) was exposed to only 10 min. of Q or N, performing both C and E tests immediately following entry into the experimental sound room: a second group of 16 *S*s (Group 2) performed both C and E tests in the last 10 min. of a 30-min. exposure to N and Q. The *S*s in the latter group read magazines prior to the tests during the first 20 min. of both the N and Q conditions. In each condition, *S* did both E and C tests for the 5-min. period allowed. Half of the *S*s in each group were tested in N on their first test day and half in Q. On each test day half of the *S*s had the E test first and half had the C test first. Both tests were scored in terms of number of lines responded to correctly. All [illegible] were instructed before each test to work [illegible] quickly and accurately as possible, completing [illegible] lines of the test as they could. The *S*'s score [illegible] displayed in a group chart on the wall near him [illegible]

Results

The number of lines completed [illegible] analyzed using analysis of variance [illegible] Experiment I, and Wilcoxon's test. [illegible]he *S*s worked faster on their second test than on their first on E sheets ($p < .001$) and on C sheets ($p < .02$), Wilcoxon's test. Every *S* worked more slowly on the [illegible] than the C test in every condition. As Table 2 shows, there was a tendency for *S*s to work slower on the C sheets and faster on E sheets in the 10-min. exposure to N, as compared to Q. On the other hand, the group with 30-min. exposure tended to work slower on E sheets and faster on C sheets in N as compared to Q. None of these differences were reliable however. The changes in speed were about 7% on E sheets and about 1% on C sheets.

The differences in number of items correctly completed on E and C tests in each condition were used to assess the interference caused by N as compared to Q. The *S*s made very few errors on either test. The average number of errors on each C and E test was less than 1. Taking the difference, or interference score, between C and E tests, there was no overall effect of N as compared to Q. There was however, a strong interaction between Interference and Duration of Exposure to N and Q, $F\ (1, 30) = 15.81$, $p < .001$. This interaction occurred because the interference, or difference between C and E tests, was less in the N condition (45.13) than in the Q condition (55.50) in the first 10-min. exposure, $F\ (1, 30) = 7.46$, $p < .025$. Only 2 out of 16 *S*s did not show less interference in N. However, considering the other group of *S*s, there was more interference with the 30-min. exposure to N (57.82) than in Q (40.00), $F\ (1, 30) = 8.38$, $p < .01$. Again, only

[2] This monochromatic control was selected in preference to material containing stimuli of different colors for ease of duplication and preparation, with a view to possible large-scale use of the test in the future. This experiment was part of a program of evaluation of the test for use in field studies of environmental stress.

2 out of 16 *S*s did not show greater interference in the 30-min. exposure to N than to Q. These 2 effects of noise did not relate systematically to either the order in which N and Q conditions were received or the order in which the 2 tests were received. Neither could there be any effect of instructional bias upon the group since not all members of a group had C and E tests presented in the same order.

TABLE 2

Mean Number of Lines Completed under Each Cindition

Group	Stimulus sheet	
	Control	Experimental
	Quiet condition	
1	170.13	114.63
2	172.44	132.44
	Noise condition	
1	169.38	124.25
2	176.88	125.06

Note. Group 1 *S*s were exposed to only 10 min. of either quiet or noise; Group 2 *S*s were tested after 20 min. of a 30-min. exposure to quiet or noise.

Discussion

The second version of the Stroop test is clearly more sensitive than the card-sorting version. In both experiments, nearly all the change in interference was contributed by performance on the experimental rather than the control material. The *S*s in Experiment II showed a much more reliable change in interference than those in Experiment I, notwithstanding the higher sound-pressure level in the first experiment. This is probably due in part to the much smaller motor and larger perceptual component in the test in Experiment II.

In addition, in the first experiment, the response of sorting by color was unrelated to the semantic description of the hue. In Experiment II, although *S* did not verbalize, he selected the appropriate semantic response in relation to the hue. Pritchatt (1968) considered 2 conditions similar to these experiments and also obtained considerably more interference when *S* was required to press a key labeled by color name rather than hue. The difference in interference between the 2 versions is generally consistent with the view of Hock and Egeth (1970) that much of the interfering effect is due to disruption of the encoding of the name of the hue by the verbal dimension of the stimulus or its aftereffect.

The effect of noise on this interference depends on duration of exposure; interference was reduced by the short exposure, confirming the results of O'Malley and Poplawsky (1971). The increased impairment during the long exposure is consistent with the change in performance in other tests during a long exposure to noise, where impairment has increased with exposure. Hartley (1973) has found that a 40-min. exposure to noise causes impairment in a serial reaction test performed only in the last 20 min. of the exposure. This impairment was worse than when 20 min. of noise was presented in the last half of 40 min. of performance. These results indicated that continuous noise led to a progressive increase in impairment, independent of task duration. In Experiment II, the difference in performance between the brief and the long exposure may also be construed as further evidence that the effect of noise on performance changes with exposure. Impairment appeared following the long exposure without any prior performance.

There is some evidence to connect the difference in interference between short and long exposure to noise with changes in arousal. Agnew and Agnew (1963) and Tecce and Happ (1964), using threat of electric shock, and Callaway (1959), using an amphetamine, obtained results indicating reduced interference under these conditions. On the other hand, Callaway (1959), using amylobarbital, and Ostfeld and Aruguete (1962), using hyoscine, obtained results indicating increased interference under these conditions. It would be reasonable to assume, although without substantiating evidence, that stimulants and shock raised arousal, while the sedatives depressed arousal. The beneficial and detrimental effects of short and long exposure to noise may likewise be connected with changes in arousal level.

A significant feature of Experiment II is the absence of any auditory cues in performance of the test. Some auditory cues, either generated by *S* or by the apparatus, have been present in nearly all tests that have shown impairment in noise. Although the fact

that noise has shown its effect at the end of the test suggests that masking of these auditory cues did not contribute to the noise impairment observed, this factor could not be ruled out (Kryter, 1970). For example an interaction between time spent on the task and loss of auditory information could account for impairment in noise appearing at the end of the test. The results of Experiment II, a task with no auditory component, clearly indicate that the adverse effect of noise need not be due to the loss of these cues, particularly in view of the initial beneficial effect of noise also obtained. Nevertheless, these results do not exclude the possibility that loss of task-independent auditory information is connected with impairment when the loss is prolonged for 20 min.

VARIABILITY AND CONTROL IN DICHOTIC MEMORY [1]

STANLEY R. PARKINSON [2]

Arizona State University

Experiments are reported in which *S*s were instructed on each trial to attend to one of 2 stimultaneously presented messages. Following a procedure developed by M. P. Bryden, order of report was manipulated by requiring *S*s to either recall the attended message first and unattended message second (AU report), or the unattended message first and attended message second (UA report). While the group data of Experiments I and II provided a clear replication of Bryden's results, extensive individual differences in unattended-ear recall functions were obtained. Conventional single-channel digit spans were assessed for *S*s in Experiment III and *S*s were grouped according to their digit span. Correlations between digit span and unattended-ear performance yielded coefficients of .88 and .84 in AU and UA reports, respectively. The theoretical implications posed by the relation between digit span and dichotic memory and the increase in experimental precision which is gained by the knowledge of digit span warrant the further use of digit span as a concomitant variable in dichotic memory research.

Dichotic memory refers to a set of experimental operations in which *S*s are given 2 different lists of items simultaneously, one to each ear, with instructions to reproduce as many of the items as they can following list presentation (Broadbent, 1971).

In the special case of the dichotic experiment where stimulus presentation is rapid (1½–2 pair/sec) and where both lists consist of a single stimulus type (e.g., digits) recorded in the same voice, *S*s tend to report items from one ear and then from the other ear (ear-by-ear report) rather than reporting items by pair (pair-by-pair report) according to their order of arrival (Broadbent, 1954; Bryden, 1962). When forced to recall pair by pair under these stimulus conditions, accuracy levels are decreased.

The reliability of these findings motivated Broadbent (1971) to formulate a model for dichotic memory performance. Broadbent proposed the existence of 2 systems: an "S" or storage system capable of parallel processing and thus of holding information received by 2 ears simultaneously, followed by a "P" or perceptual system limited to sequential information processing. According to the model, auditory–verbal information enters the organism via the S system. A selective filter, operating in time between the S and P systems, selects the message from one ear for entry into the P system and attenuates processing of the message received by the other ear. The P system processes (categorizes) the selected ear message and that message is reported first during recall. The initially unselected message is held in the S system until processing of the first message has been completed, at which time it gains access to the P system. Another way of stating the operation of the model is that an individual attends to and rehearses the message received by one ear (P system) while the message received by the other ear is held in a very-short-term buffer or echoic store (S system). Following recall of the attended message, *S* shifts his attention to and recalls the second message.

As Broadbent (1971) has noted, the S and P system nomenclature is somewhat misleading as the S system is viewed as a parallel processing system while the P system is assumed to be sequential in operation. Due to this confusion, and to

[1] This research was supported in part by the U.S. Air Force Human Resources Laboratory, monitored by the Flying Training Division under Contract F-41609-72-C-0037. The author wishes to express his gratitude to Lora Hubbard for her assistance in all phases of this research.

more closely align the terminology with other memory models, the term "echoic store" (Neisser, 1967) will be used when referring to a very-short-term auditory buffer in which information is relatively unanalyzed (S system), and "active store" (Kroll, Parkinson, & Parks, 1972; Sternberg, 1969) will be used when referring to a system consisting of attention and rehearsal processes (P system).

A finding of major importance for the present purpose is that recall accuracy for the ear reported second in dichotic memory tasks is generally lower than that for the ear reported first (e.g., Bryden, 1964). In terms of the model under consideration this finding implies that the echoic store is (*a*) limited in duration, and/or (*b*) limited in capacity, and/or (*c*) vulnerable to either input or output interference (or both) resulting from first-ear processing.

Broadbent (1957) conducted an experiment in which the 2 messages of dichotic pairs differed in length. The message to the ear to be reported first consisted of 6 digits, while 2 digits were presented to the ear to be reported second. In order to test a decay or limited duration hypothesis, the 2-digit message was presented simultaneously with either the first 2, middle 2, or final 2 digits of the 6-digit message. Presentation rate was 2 pair/sec, making the difference in time between the extreme conditions on the order of 2 sec. Broadbent found more accurate recall when the 2-digit message coincided in presentation with the final 2 digits of the 6-digit message, a result which is consistent with the hypothesis that echoic storage is subject to rapid decay (1–2 sec.).

A similar time estimate was offered by Murray and Hitchcock (1969). They instructed *S*s to either silently code (without observable mouth movement) or mouth code (articulate silently) one of a pair of 5-digit messages presented dichotically. In a third group, labeled the "not code group," *S*s were instructed to say *the* as each pair of stimuli arrived. At the end of each stimulus list, *S*s were probed for their retention of a single digit on either the "coded" or "uncoded" message. Murray and Hitchcock found that, even with a probe recall procedure which minimizes response interference, only one item was recalled above chance levels in the uncoded message of the silently-code and mouth-code groups and in both messages of the not-code group. Given the stimulus presentation rates employed (1 and 2 pair/sec), they estimated that the duration of echoic storage was between 1 and 2 sec.

In another series of experiments directed towards determining the temporal parameters of echoic storage, however, Bryden (1971) obtained results which suggest that the time course of echoic storage is considerably longer (several seconds) than previously indicated. Using a dichotic memory procedure, Bryden instructed his *S*s to "attend" to one ear (either left or right) during list presentation. Order of report was manipulated by instructing the *S*s to either recall attended ear first and unattended ear second (attended–unattended or AU order), or to recall unattended ear first and attended ear second (UA order). Bryden argued that if unattended ear items were retained in an echoic store of very brief duration (1–2 sec.), recall should be impaired when they were reported second (AU) relative to a condition in which they were reported first (UA).

The results which Bryden (1971) obtained were not in accord with his hypothesis; i.e., the accuracy of unattended-ear recall did not vary as a function of order of report. Positively increasing serial position functions were found with unattended-ear recall regardless of order of report. Serial position functions on the attended ear were relatively flat with both report orders, but unlike the unattended ear, attended-ear recall was impaired when reported second. This latter result would be expected if it were assumed that attended-ear items were retained in a rehearsal-dependent active store, as reporting of unattended items in UA reports would prevent rehearsal of attended-ear items.

Bryden (1971) attempted to explain his failure to detect a difference between unattended-ear recall as a function of order of report (and to retain the notion of an echoic store) by making 3 assumptions: (*a*) The S system or echoic memory lasted longer than the delay of reporting U items in AU reports; thus, no impairment of unattended items occurred. (*b*) Echoic storage is less vulnerable to output interference than is active storage. This follows from his finding that the difference between attended reports ($A_1 - A_2$) was greater than the difference between unattended reports ($U_1 - U_2$). (*c*) The echoic store is of limited capacity (1–2 items). The latter interpretation was derived from the positively increasing serial position functions obtained with unattended-ear recall.

The present series of studies represents an attempt to further study the nature of recall processes in dichotic memory. The first experiment reported here was a replication of the Bryden (1971) procedure, in which attention and recall instructions were manipulated in a within-*S*s design. In the second experiment objective measures of attention instructions were obtained by requiring *S*s to either write down or verbalize the attended-ear message as it was presented. The third experiment was concerned primarily with providing a means for accounting for some of the variability in dichotic memory performance by grouping *S*s according to conventional digit spans.

Experiment I

Method

Subjects. Twelve students enrolled in an introductory experimental psychology course at Arizona State University served as *Ss* in the present experiment. The *Ss* were all right-handed and varied in age from 19 to 25 yr.

Materials and apparatus. Subjects were tested individually in a sound reduction chamber. Subjects received 42 dichotic lists each consisting of 2 different lists of 4 digits presented simultaneously, one to each ear. Both channels (left and right) were recorded by the same male speaker at the rate of 2 pair/sec. Stimulus lists were recorded on a TEAC model TCA 42 4-channel tape deck and they were played to *S* through stereo headphones (Superex Pro-BV). The stimulus lists were constructed from the set of numbers 0–9 and no number appeared twice on a given trial.

Procedure. Each *S* was instructed to attend exclusively to one ear and to ignore the other ear during stimulus presentation, even though messages to both ears were to be recalled. One half of the *Ss* were told to attend to the right ear and one half were told to attend to the left ear. The ear of attention remained constant for each *S* during the course of the experiment.

Subjects received 2 blocks of 21 trials, each block consisting of 5 practice trials followed by 16 test trials. During the first block of trials, 6 *Ss* (3 attending to their right ear and 3 to their left ear) were instructed to recall the digits in the attended ear first and then to recall the digits in the unattended ear (AU order), while the remaining 6 *Ss* (again 3 right ear and 3 left ear) were given instructions to recall first the digits in the unattended ear followed by the digits in the attended ear (UA order). All *Ss* were reversed in the second block of 21 trials: those reporting AU in the first block reported UA in the second while those reporting UA initially were told to report AU in the second block.

Serial recall instructions were given in all conditions; i.e., in AU reports *Ss* were instructed to recall the attended-ear digits in the order in which they were received and then to recall the unattended-ear digits again in the order received. While *Ss* were instructed to recall as many of the digits as they could remember on each trial, no attempt was made to force *Ss* to recall all 8 digits. If an *S* remembered only 2 unattended-ear digits, he was encouraged to report only those 2 in the order in which they were presented. Consider an example in which the unattended message was 6, 8, 4, 2. If the *S* remembered only 4 and 2, he was instructed to report only 4 and 2. It was thought that if *Ss* were encouraged to guess, and thereby to report more items, the additional response interference might cause them to forget the items which they did remember. For the same reason, in the previous example, *Ss* were not instructed to say ***blank, blank***, 4, 2, even though that type of report would have given a more accurate indication of serial position.

No attempt was made in this experiment to objectively determine if *Ss* were in fact following the attention instructions (i.e., if *Ss* were attending to only one ear during stimulus presentation). Order of report instructions, however, was closely monitored. If *Ss* reported in reverse order (e.g., AU in a UA condition), the tape was stopped and *Ss* were reminded that order of report was important. This procedure proved to be successful, as reversals of this type occurred in less than 1% of the total observations.

Results

While *S*s were instructed to recall as many of the digits as they could in the

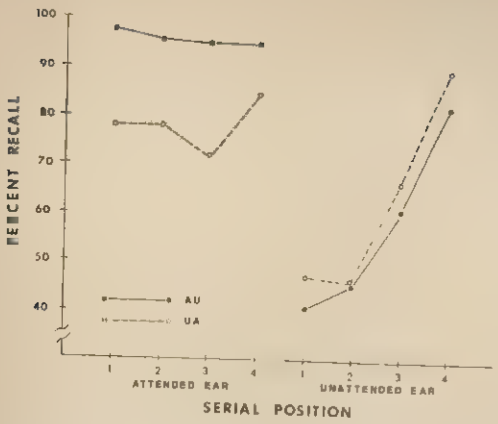

FIGURE 1. Group data, Experiment I: percentage correct recall as a function of attention (attended–unattended ear), order of report (attended–unattended, AU; unattended–attended, UA) and serial position.

order in which they were received (serial recall), incomplete reports occurred in the majority of trials. As there is no adequate way to deal with omissions in serial recall, a free-recall scoring procedure was used. Items were scored as correct in the serial position in which they were presented if they were recalled in the correct ear. Consider the following examples in which the attended message was 4, 5, 9, 1, and the unattended message was 2, 6, 3, 8. If, given an AU report instruction, *S* reported 4, 5, 9, 1, 2, 6, 3, 8, he received a perfect score on both his attended and unattended ears. If an *S* reported 4, 5, 9, 1, 3, 8, he received a perfect attended-ear score and 3 and 8 were scored as correct in the third and fourth serial positions, respectively, on the unattended ear. If an *S* reported 4, 9, 5, 1, 2, 8, he still received a perfect attended-ear score, even though 9 and 5 were transposed, and 2 and 8 were scored as correct responses in the first and fourth serial positions, respectively, on the unattended ear.

Raw scores were converted to percentage correct recall and a 2 Between × 3 Within analysis of variance was computed. In this analysis, the ear of attention (left or right) and the sequence of report instructions (AU–UA or UA–AU) were between factors while report instructions (AU and UA), attention (A and U), and serial position (1, 2, 3, 4) were within-groups facto[r]

The results obtained in this experime[nt] (see Figure 1) were remarkably similar [to] those obtained by Bryden (1971, Figure [5]). Neither of the between factors ear of [at]tention or sequence of report instructions produced reliable differences; however, ea[r] of attention (right ear superiority) approached significance, F (1, 8) = 2.5[?], $p = .149$, $MS_{\text{Error}} = 1{,}283.86$.

Performance on the attended [ear] w[as] superior to performance on the una[ttended] ear, F (1, 8) = 27.47, $p < .001$, $MS_{[\text{Error}]}$ = 1,282.78, and as in the Bryden (19[71]) study there was a significant interaction b[e]tween attention and serial position, F (3, 24) = 13.43, $p < .001$, $MS_{\text{Error}} = 322.41$. The serial position functions for the attended ear, whether reported first or second, were relatively flat, while positively increasin[g] serial position functions were obtained fo[r] the unattended ear. The Order of Repo[rt] × Attention interaction was significan[t], F (1, 8) = 26.65, $p < .001$, $MS_{\text{E}[\text{rror}]}$ = 230.91, indicating a greater differen[ce] between attended-ear scores ($A_1 - A_2$) than between unattended-ear scores ($U_1 - U_2$).

The group data are fully consistent with the findings of Bryden (1971). The failure to detect a difference in unattended-ear recall as a function of order of report is compatible with the hypothesis that echoic storage lasts for several seconds. The positively increasing serial position functions obtained with unattended reports suggests that the echoic store is limited in capacity.

However, while the group data were supportive of the Bryden (1971) findings and interpretations, there was extensive between-*S*s variability in the present experiment. The individual functions of all 12 *S*s are shown in Figures 2 and 3. With regard to the unattended ear, it can be seen that the 6 *S*s in Figure 2 have individual functions which reflect the group performance shown in Figure 1. These 6 *S*s all show unattended-ear performance to be a positively increasing function of serial position. The 6 *S*s shown in Fig-

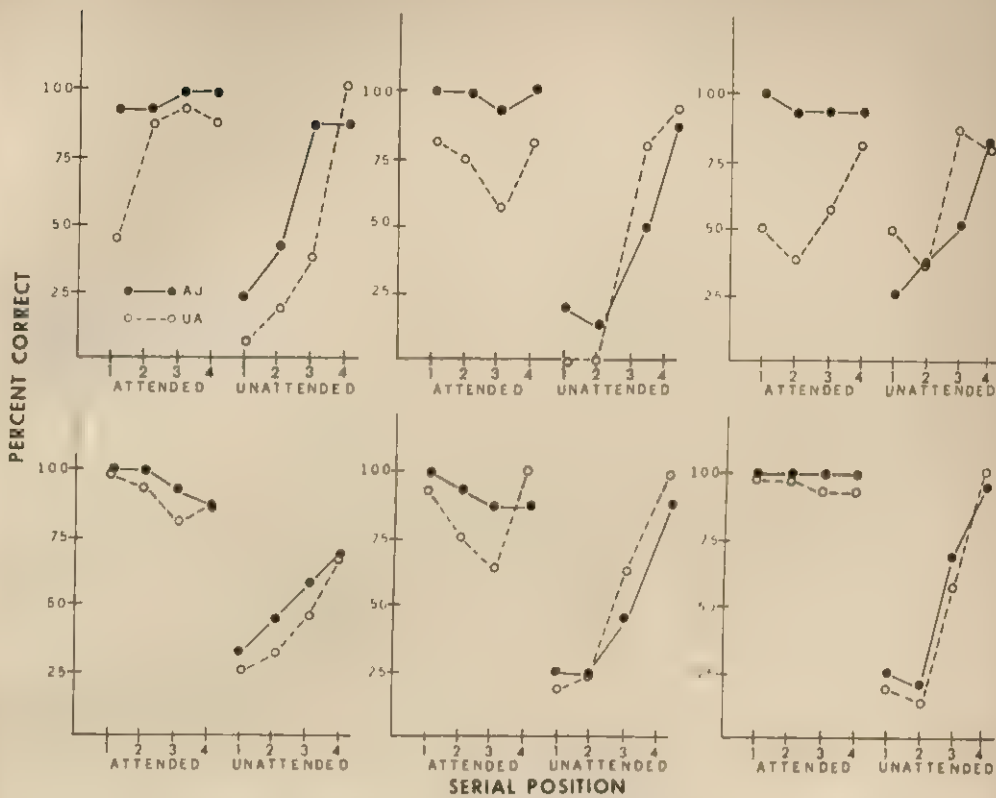

FIGURE 2. Individual data, Experiment I: percentage correct recall as a function of attention (attended unattended ear), order of report (attended unattended, AU, unattended attended, UA), and serial position.

ure 3, however, show individual unattended-ear functions which are widely divergent from the group average.

In an attempt to determine the source of variability between *S*s, a more detailed analysis of the response patterns was made. In the AU order of report, all 12 *S*s responded with 4 digits from the attended ear before switching to the unattended ear. This response pattern was obtained in 190 of the 192 trials.

In contrast to the consistency found between *S*s in AU reports, there was considerable variability in UA reports. Five *S*s responded with an average of 2 or fewer U items in UA reports, while the remaining 7 *S*s responded with an average of 4 U responses. All of the 5 *S*s responding with 2 or fewer U responses showed positively increasing serial position functions on the unattended ear, while 6 of the 7 *S*s responding with 4 U items showed a pronounced absence of that effect. Whether or not recall accuracy on the unattended ear is a positively increasing function of serial position is dependent on the number of items reported from that ear.

The variability in unattended-ear performance in this experiment precludes any definitive theoretical statement about the properties of echoic storage. What experimental operations or designs might be employed in order to reduce or to account for this variability?

EXPERIMENT II

In the second experiment *S*s were again instructed to attend to only one ear (balanced left or right over *S*s) during stimulus presentation. In order to insure more objectively that *S*s were following the instructions, *S*s were told to either

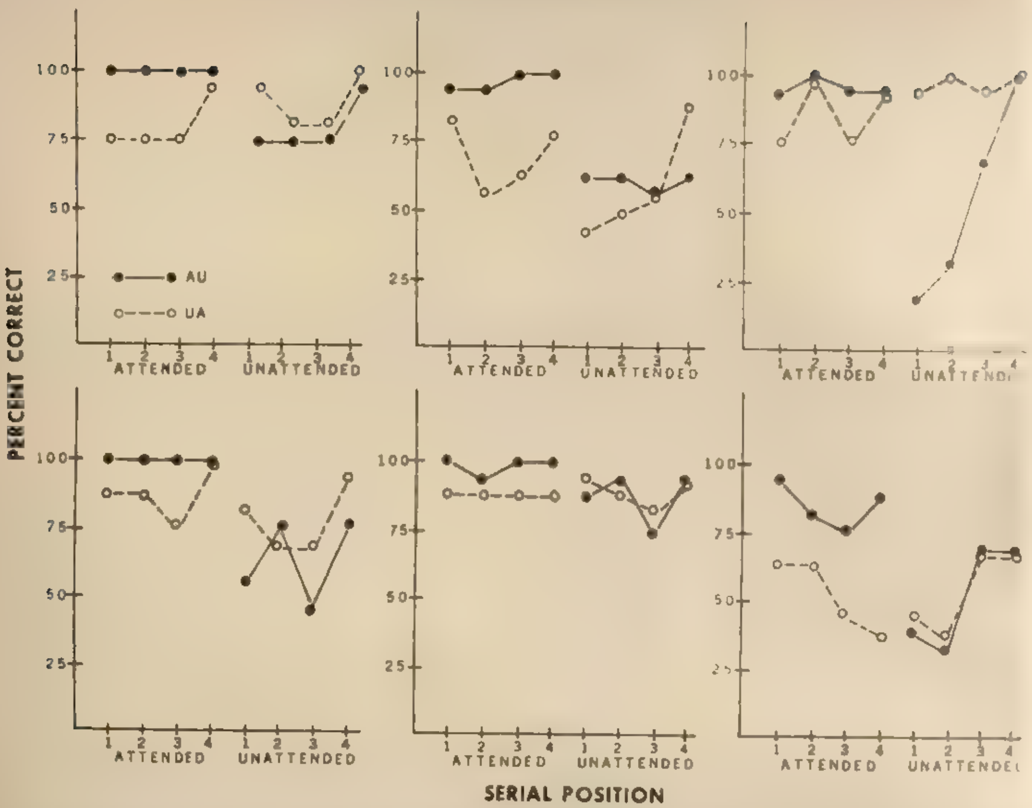

FIGURE 3. Individual data, Experiment I: percentage correct recall as a function of attention (attended–unattended ear), order of report (attended–unattended, AU; unattended–attended, UA), and serial position.

write down or verbalize the message received by the attended ear as it was presented.

If failure to follow the attention instructions contributes to the variability found in this type of task, then in Experiment II a disparity in recall functions should exist between conditions in which *S*s follow instructions (attended message perfectly monitored during stimulus presentation) and when they do not (imperfect monitor of attended-ear message).

Another reason for conducting the second experiment concerns attended–unattended performance as a function of type of monitor. Both the overt acts of verbalizing and writing a message during presentation constitute types of rehearsal. Given that attended-ear performance is mediated by an active storage system, comprised of attention and rehearsal processes, both monitor types should result in uniformly high attended-ear performance. If unattended-ear performance is mediated by an echoic store in which information is relatively unanalyzed, subsequent auditory stimulation might be expected to interfere with the maintenance of and/or recall from this system. A monitor which produces further auditory stimulation by way of auditory–verbal feedback (verbal monitor) might, therefore, result in more interference than a monitor which does not contribute auditory stimulation (written).

Method

Subjects and apparatus. Twenty-four students enrolled in an introductory experimental psychology class served as *S*s in this experiment. The materials and apparatus employed were identical to those of the first experiment.

Procedure. Subjects were randomly assigned to one of 2 groups: verbal monitor and written monitor. Each *S* was told to attend to only one ear during stimulus presentation. One half of the *S*s

TABLE 1

PERCENTAGE CORRECT RECALL, EXPERIMENT II, FOR WRITTEN AND VERBAL GROUPS, WITH AND WITHOUT PERFECT MONITORING

Group	Attended		Unattended	
	Perfect	With errors	Perfect	With errors
Written	90.81	88.74	67.28	65.66
Verbal	93.62	91.40	43.00	39.30

in each group were instructed to attend to the right ear and one half were told to attend to the left ear. As in the first experiment the ear of attention for each S remained constant during the course of the experiment.

Subjects received the same 2 blocks of 21 trials as those used in the first experiment. The sequence of instructions for recall, AU–UA and UA–AU, was balanced for both groups.

Written monitor. Subjects were instructed to write down the attended-ear message as it was presented. During this task S inserted his right arm through an aperture in a wooden stand. A piece of black opaque plastic around the aperture prevented S from seeing his written response. While S was writing his attended-ear response, E observed both the S and the VU meter in the preamplifier to insure that the written monitor was synchronized with the presentation of the message. After a few practice trials Ss started in the 2 blocks of 21 experimental trials.

Verbal monitor. Subjects were told to verbally monitor the attended-ear message. The E wrote down the verbal monitor as well as the verbal recall response for the attended and unattended ears. Again E observed the VU meter in an attempt to insure synchrony of verbal monitor and stimulus presentation.

Results

The first question posed with regard to this experiment asked if failure to follow instructions (shown by an imperfect monitor) were a factor contributing to performance variability. If it were, a disparity in recall functions should be observed when Ss followed instructions (perfect monitor) and when they did not (imperfect monitor). These scores (collapsed over serial position) were obtained for each individual, and the group means are shown in Table 1. Correlated t tests showed all of these differences to be unreliable, all ps $> .05$. All trials with perfect and imperfect monitors were included in further analyses.

As in the first experiment, a free-recall scoring analysis was used. Raw scores were converted to percentage correct recall and a 3 Between $\times$ 3 Within analysis of variance was conducted. This analysis was the same as that in the first experiment, with the addition of type of monitor as a third between-Ss variable.

The results shown in Figures 4 and 5, depicting performance for the written and verbal monitor groups, respectively, indicate that as in the first experiment (*a*) attended-ear recall was superior to unattended-ear recall, F (1, 16) = 112.60, $p < .001$, MS_{Error} = 1,131.48; (*b*) the Attended–Unattended Ear $\times$ Serial Position interaction was significant, F (3, 48) = 76.94, $p < .001$, MS_{Error} = 130.66, with attended-ear serial position functions flat and unattended-ear functions positively increasing; and (*c*) the Order of Report (A–U vs. U–A) $\times$ Attention (A vs. U) interaction was reliable, showing a greater difference between attended-ear reports than between unattended-ear reports, F (1, 16) = 20.95, $p < .001$, MS_{Error} = 141.94.

Of more interest in the present results are the effects of type of monitor on various aspects of recall patterns. While the written monitor group was superior to the verbal monitor group, F (1, 16) = 18.70, $p < .001$, MS_{Error} = 553.29, the difference was due solely to the unattended ear. The interaction (shown in Figure 6)

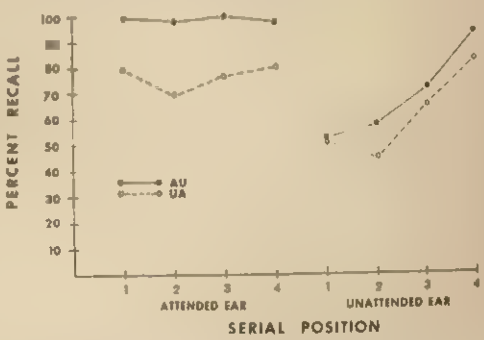

FIGURE 4. Written monitor group, Experiment II: percentage correct recall as a function of attention (attended–unattended ear), order of report (attended–unattended, AU; unattended–attended, UA), and serial position.

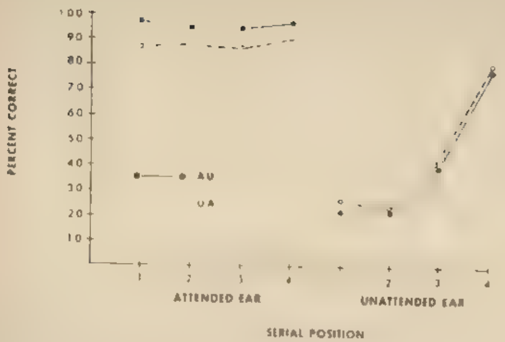

FIGURE 5. Verbal monitor group, Experiment II: percentage correct recall as a function of attention (attended–unattended ear), order of report (attended–unattended, AU; unattended–attended, UA), and serial position.

between type of monitor and ear of report was reliable, F (1, 16) = 17.49, $p < .001$, $MS_{\text{Error}} = 1{,}131.48$, as was the triple order interaction between type of monitor, ear of report, and serial position, F (3, 48) = 4.41, $p < .008$, $MS_{\text{Error}} = 130.66$.

These results, showing both differential recall functions for attended and unattended ear and selective impairment of unattended-ear recall with a verbal monitor, are compatible with a dual storage model in which attended-ear performance is mediated by an active store and unattended-ear performance is mediated by an echoic store. While interesting, however, the results of this experiment did not contribute to understanding of the mecha-

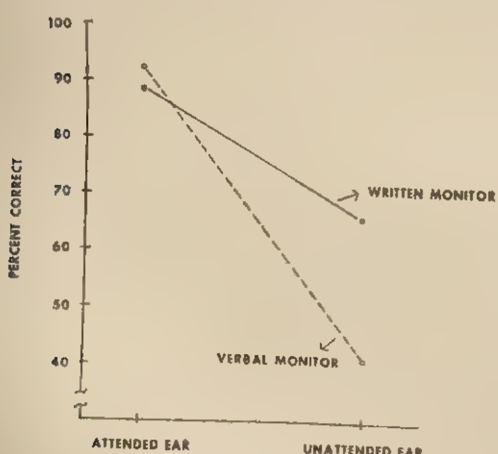

FIGURE 6. Percentage correct recall as a function of type of monitor and attention.

nisms underlying variability in dicho memory performance.

On reexamination of the individual d shown in Figures 2 and 3, it was obvi that some *Ss* were recalling more ite than were others. Perhaps this dispari in number of items recalled was a functi of capacity, with variability in dichot memory performance being determined l individual differences in "immediate mem ory span" (Miller, 1956).

In order to test the capacity hypothesi digit spans were assessed for each *S* Experiment III and *Ss* were grouped cording to digit span.

EXPERIMENT III

Method

Tests of digit span were administered to potential *Ss* entering the laboratory. The stin for measuring spans consisted of 5 sets of each set being comprised of 2 lists of each len ranging from 3 to 15 digits. Each *S* was te individually and received all 5 list sets. Stim presentation was binaural and presentation was set at 2 digit/sec. During each span assess ment, *Ss* received an ascending series of lists with instructions to reproduce each list in the corr t order immediately following its termination. This procedure continued until an *S* erred on both lists of a given length, at which time his digit span was assigned as one less than that number (e.g., if an *S* missed both lists with 8 digits, his digit span for that list set was 7). Each *S* was assigned an average digit span following 5 such assessments. In order to be included as an *S* in this experiment, certain criteria had to be met. The 5 digit spans for an *S* had to exhibit a clear mode; 3 of the 5 span estimates had to be identical. In addition, no single span estimate could vary by more than one unit from the mode. Thus, while scores of 6, 5, 6, 7, 6 resulted in a digit span of 6, a set of scores such as 5, 7, 6, 7, 7 resulted in exclusion from the experiment, as 5 was 2 units less than the mode of 7. This criterion is rather strict and it resulted in the exclusion of many individuals, but in a first approximation towards determining the effects of digit span in dichotic memory performance, a strict criterion was thought to be advisable.

It seemed essential to cover a wide range of spans, so the design was set for groups with span estimates of 5, 6, 7, 8, 9, and 10 digits. The attempt to get 8 *Ss* per group was successful for spans of 6, 7, 8, and 9; however, only 4 *Ss* were obtained for the 5- and 10-digit groups. Therefore, a total of 40 *Ss* was included in this experiment.

Subjects within all digit-span groups were balanced with regard to both ear of attention (left

or right) and order of report sequence (AU–UA, UA–AU).

The instructions and experimental procedure were identical to those of the first experiment with the following exceptions: (*a*) each *S* received 10 practice trials prior to a test block, and (*b*) each test sequence included 30 trials. Therefore, in this experiment each *S* received 20 practice ists and 60 test lists.

Results

The results for all *S*s are shown (*a*) collapsed over digit-span groups for both AU and UA reports in Figure 7, and (*b*) as a function of digit-span group for AU and UA reports in Figures 8 and 9, respectively. While all of the digit-span groups are included in the figures, in order to retain equal group size only the groups comprised of 8 *S*s each (i.e., Digit-Span Groups 6, 7, 8, and 9) were included in the analysis of variance. It is obvious from Figures 8 and 9 that any difference detected between digit-span groups would be accentuated by the addition of Groups 5 and 10.

Examination of Figure 7 reveals results comparable to those obtained in Experiments I and II. Indeed, as in the other

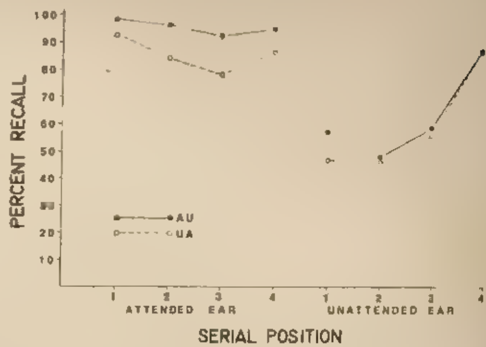

FIGURE 7. Group data, Experiment III: percentage correct recall as a function of attention (attended–unattended ear), order of report (attended–unattended, AU; unattended-attended, UA), and serial position.

experiments the following results were reliable: (*a*) the AU order produced higher recall than the UA order, F (1, 16) = 24.52, $p < .001$, $MS_{\text{Error}} = 245.01$; (*b*) attended ear was superior to unattended ear, F (1, 16) = 258.90, $p < .001$, $MS_{\text{Error}} = 434.48$; (*c*) terminal serial positions were more accurately recalled than initial serial positions, F (3, 48) = 55.43, $p < .001$, $MS_{\text{Error}} = 196.66$, a result which is due primarily to the positively increasing

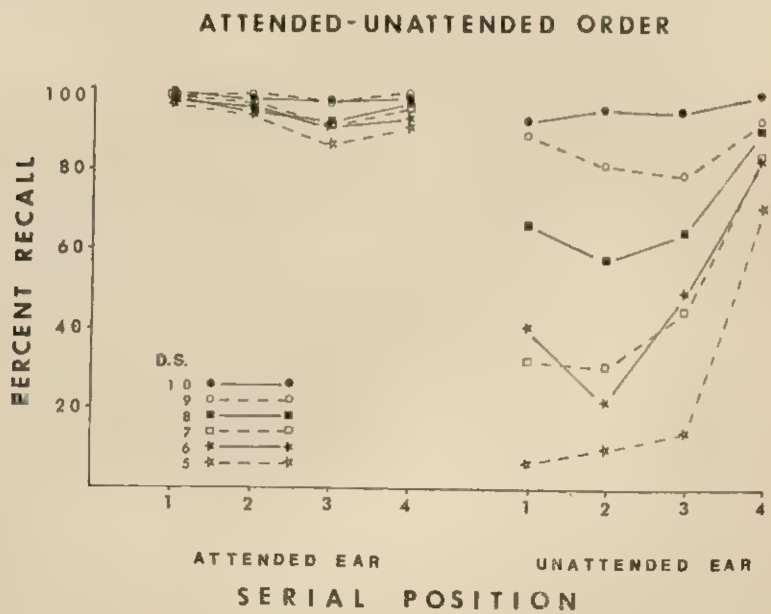

FIGURE 8. Percentage correct recall with the attended–unattended report order as a function of digit span (DS), attention (attended–unattended ear), and serial position.

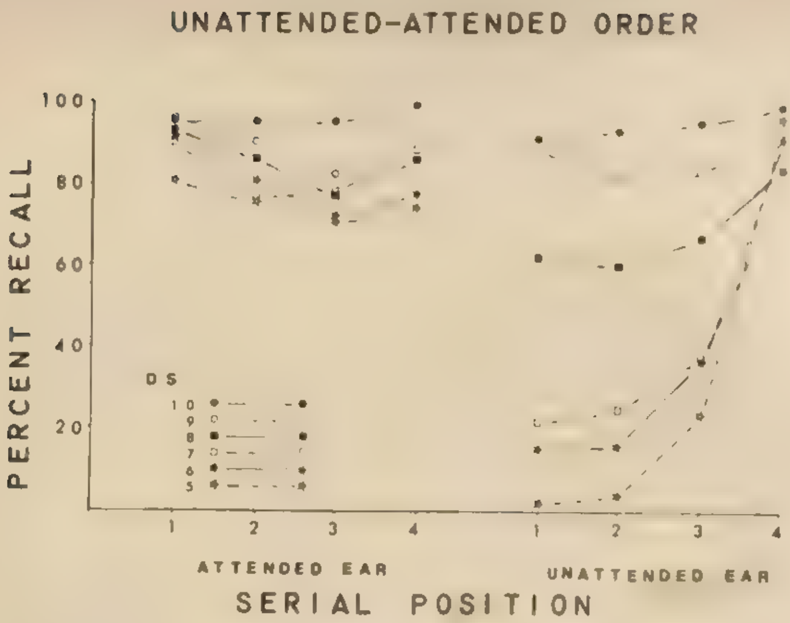

FIGURE 9. Percentage correct recall with the unattended-attended report order as a function of digit span (DS), attention (attended-unattended ear), and serial position.

serial position functions in the unattended ear, F (3, 48) = 58.18, $p < .001$, MS_{Error} = 193.51; and (d) there was a greater disparity between attended-ear scores when reported first and second than between unattended-ear reports as a function of report order, F (1, 16) = 7.45, $p < .01$, MS_{Error} = 215.60.

The effect of digit-span groups as a between-*Ss* variable is highly reliable, F (3, 16) = 23.24, $p < .001$, MS_{Error} = 742.74; and while there is a small effect of digit span on the attended ear when reported second, the most substantial effect of digit span is on unattended-ear performance. This was confirmed in statistical analysis by a Digit Span × Attended–Unattended Ear interaction F (3, 16) = 23.88, $p < .001$, MS_{Error} = 434.48, a Digit Span × Serial Position interaction, F (9, 48) = 5.76, $p < .001$, MS_{Error} = 196.66, and a Digit Span × Attention × Serial Position interaction, F (9, 48) = 7.21, $p < .001$, MS_{Error} = 193.51.

TABLE 2

COEFFICIENTS OF CORRELATION AND DETERMINATION BETWEEN ATTENDED-EAR AND UNATTENDED-EAR RECALL ACCURACY AND DIGIT SPAN

Reports	Attended ear		Unattended ear	
	r	r^2	r	r^2
Attended–unattended	.474	.225	.881	.776
Unattended–attended	.625	.391	.844	.712

While reliable, the interactions do not provide us with any indication of the strength of the relationship between digit span and dichotic memory performance. The total number of items correct in the dichotic task was calculated for each S (N = 40), and the correlation between digit span and dichotic performance was determined. This analysis yielded a very high correlation coefficient, r = .891. The coefficient of determination (Hays, 1963), r^2, gives an indication of the strength of the linear relationship between 2 measures. The coefficient in the present experiment indicates that 79.39% of the variance in dichotic memory can be accounted for by a linear rule and digit span. In Table 2 separate coefficients of correlation and determination are given for each measure of dichotic performance, i.e., for attended- and unattended-ear recall in both AU and

UA reports. These figures indicate that most of the variance accounted for by digit span is in unattended-ear recall.

In the first experiment, the nature of the unattended-ear serial position functions was shown to be due in part to differential report strategies. Positively increasing serial position functions were obtained when the mean number of unattended items reported was 2 (Figure 2), while more variable functions were obtained when an average of 4 unattended items was reported (Figure 3). The *S*s in Figure 2 were therefore making errors of omission, while the *S*s in Figure 3 were making primarily errors of commission, either in the form of interlist or extralist intrusions. An error analysis for the *S*s in the present experiment is provided in Table 3. In this table the number of errors is shown as a function of digit-span group and attention (attended–unattended ear). Errors were divided into 3 types: omissions—items presented on either the attended or unattended ear which were not reported during recall; interlist intrusions—items presented on the attended ear which were recalled as unattended items and items presented on the unattended ear which were reported as attended ear items; extralist intrusions—items reported during recall which were not members of the stimulus set.

As shown in Table 3, while low-span *S*s made more attended-ear errors than did high-span *S*s, no apparent differences were evident in the pattern of errors made by *S*s in the various digit-span groups. However, on the unattended ear there was an orderly trend of type of error as a function of digit span. Approximately 90% of the unattended errors made by *S*s with digit spans of 5, 6, and 7 were errors of omission, i.e., items were simply not reported during recall. This tendency was still prominent for *S*s with a digit span of 8, as 74% of the errors were omissions. Between Spans 8 and 10, however, there was a shift in the type of errors, with a reduction in errors of omission and an increase in errors of commission, so that by Span 10 the majority of errors were interlist intrusions.

TABLE 3

TYPE OF ERROR (OMISSIONS, INTERLIST INTRUSIONS, AND EXTRALIST INTRUSIONS) AS A FUNCTION OF ATTENTION AND DIGIT SPAN, EXPERIMENT III

Digit span	Omissions		Interlist intrusions		Extralist intrusions	
	No.	%	No.	%	No.	%
Attended ear						
5 ($n = 4$)	134	44.37	156	51.66	12	3.97
6 ($n = 8$)	213	50.84	193	46.06	13	3.10
7 ($n = 8$)	167	47.72	170	48.57	13	3.71
8 ($n = 8$)	116	42.96	135	50.00	19	7.04
9 ($n = 8$)	73	42.44	86	50.00	13	7.56
10 ($n = 4$)	12	29.27	23	56.10	6	14.63
Unattended ear						
5 ($n = 4$)	576	89.44	59	9.16	9	1.4
6 ($n = 8$)	932	91.46	78	7.66	10	.98
7 ($n = 8$)	904	89.33	93	9.19	15	1.48
8 ($n = 8$)	482	74.04	150	23.04	19	2.92
9 ($n = 8$)	219	54.89	154	38.59	26	6.52
10 ($n = 4$)	31	40.79	38	50.00	7	9.21

This analysis raises the interesting problem that response strategy (which is correlated with digit span) and not digit-span ability per se might be the factor which produced the results of these experiments. Due to the large number of incomplete reports (errors of omission), I was forced to use a free-recall scoring procedure; and as high-span *S*s responded with more unattended-ear items than low-span *S*s, their recall functions might have been inflated simply due to guessing. Two questions then arise: (*a*) What would the recall patterns of high-span *S*s look like if a scoring procedure (serial recall scoring) less sensitive to guessing were employed? and (*b*) What would happen if low-span *S*s were coerced to recall 8 digits per trial? With regard to the second question, would the recall patterns of low-span *S*s become more like those shown typically by high-span *S*s (which would mean that the results obtained were primarily a function of response strategy and not digit-span ability per se), or would they remain much the same as when these *S*s recalled in a manner of their own choice (which would be more indicative of digit-span ability)?

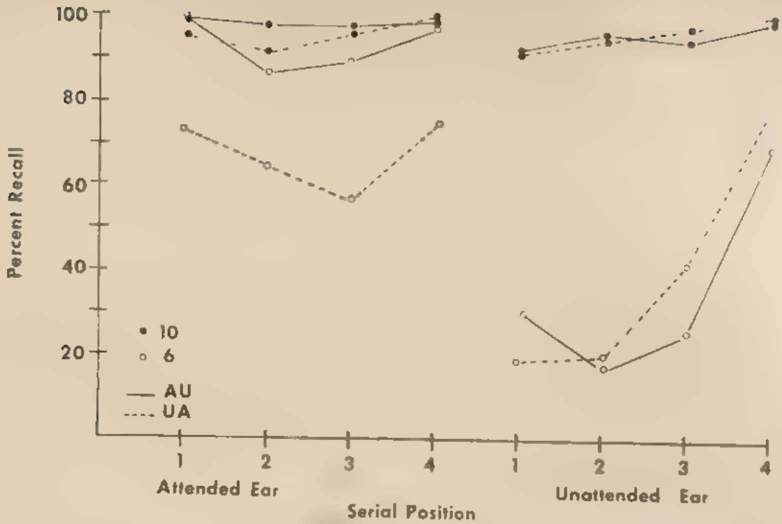

FIGURE 10. Percentage correct serial recall in Experiment IV as a function of digit span (10 or 6), attention (attended unattended ear), order of report (attended unattanded, AU; unattended attended, UA), and serial position

In the next experiment 4 *Ss* with low digit spans were forced to respond with 4 attended-ear and 4 unattended-ear digits in both AU and UA reports. This procedure permits a serial recall scoring analysis, the results of which can be compared with data from the high-span *Ss* in the last experiment.

Experiment IV

Method

Subjects and apparatus. Digit spans were assessed as in Experiment III and 4 *Ss* with digit spans of 6 were selected for participation as *Ss* in the present experiment. The apparatus was the same as that used in the previous experiments.

Procedure. Each *S* participated in 2 test sessions. In both sessions *Ss* received the test tape used in Experiment III, which consisted of 2 practice blocks (10 trials each) and 2 test blocks (30 trials each). Headphones were reversed in the second test session for all *Ss*.

In the first test session 2 *Ss* were instructed to attend to their right ear and 2 to their left ear. One *S* attending to each ear was given the report sequence AU–UA while the other *S* was given UA–AU. The instructions were the same as those previously administered, i.e., to report as many items as they could remember from both ears. As in the previous experiments *Ss* were instructed to report the items in the order in which they were presented. This test session was used to establish that the performance of these *Ss* was comparable to that of the low-span *Ss* in Experiment III.

In the second test session, *Ss* received the same test tape but with headphones reversed so that attended and unattended messages were different from those in the first session. Each *S* attended to the same ear (right or left) and received the same report sequence (AU–UA or UA–AU) as he did in the first session. The only change in the second session was in the report instructions. Each *S* was told that he was to report 4 attended-ear digits and 4 unattended-ear digits in both AU and UA reports. Subjects were told to guess if they did not remember the numbers. In addition they were instructed to make sure to report the numbers that they did remember in the correct serial position.

Results

The purpose of the first test session was simply to establish that the performance of *Ss* in the present experiment, when they were allowed to report in the manner of their choice, was comparable to that of the low-span *Ss* in Experiment III. The *Ss* in the present experiment responded with only 1 or 2 unattended-ear items in both AU and UA reports. Collapsed across *Ss* and order of report (AU and UA), their mean percentage correct recall on the unattended ear was 11.67%, 12.91%, 35%, and 83.33%, respectively, for Serial Posi-

tions 1–4. Comparison of these percentages with those shown in Figures 8 and 9 indicates that *S*s in the present experiment were comparable to the low-span *S*s in the previous experiment.

A serial recall scoring procedure was used for data in the second session, in which *S*s were required to report 4 attended-ear and 4 unattended-ear items on each trial. In this analysis a number was scored correct only if it was recalled in the correct serial position. Given an attended-ear message, 5, 9, 1, 3, and an unattended message, 4, 2, 6, 8, with an AU report instruction, if *S* recalled 5, 1, 9, 3, 4, 6, 2, 8, he was given credit only for the first and fourth serial position digits in both ears. In the free-recall scoring procedure used previously, *S*s would have received perfect credit for this report.

Raw scores from the second session were converted to percentage correct recall, and they are plotted in Figure 10. Also shown in Figure 10 is a serial recall analysis of the data for the 4 *S*s with a 10-digit span who participated in Experiment III. As these 4 *S*s all responded with 4 attended-ear and 4 unattended-ear digits on each trial, their data were simply rescored. Comparison of the data in Figure 10 with those shown in Figures 8 and 9 reveals 2 interesting findings. First, the performance of high-span *S*s remained unchanged with a serial recall scoring analysis, indicating that these *S*s were not simply guessing more items than low-span *S*s. Second, low-span *S*s were able to recall only 1 or 2 unattended ear digits in the correct position, even though they responded with 4 digits on each trial. Together these findings suggest that it is digit-span ability, and not a response strategy correlated with digit span, which is the important variable underlying differential performance.

Discussion

Several group findings were revealed reliably by analyses of variance across Experiments I, II, and III: (*a*) attended-ear recall was superior to unattended-ear recall; (*b*) attended-ear serial position functions were relatively flat, while positively increasing serial position curves characterized unattended-ear performance; (*c*) attended-ear recall was impaired when reported second relative to when reported first; (*d*) unattended-ear recall accuracy did not vary as a function of order of report; and (*e*) AU reports were superior to UA reports.

TABLE 4

Mean Number of Unattended Items Recalled Correctly per List (Collapsed over Order of Report) as a Function of Digit Span

Digit span	*M* no. of unattended digits recalled
5	1.14
6	1.78
7	1.78
8	2.80
9	3.46
10	3.80

However, of these experimental findings, only 3 were found to be reliable across *S*s of all digit-span groups: (*a*) impairment of attended-ear recall when reported second, (*b*) invariance of unattended-ear recall accuracy as a function of report order, and (*c*) superiority of AU reports. There was a pronounced absence of Serial Position × Attention interactions in high-span groups, and the tendency for attended-ear superiority was diminished.

What are the mechanisms or processes underlying digit span which result in more accurate unattended-ear performance when digit span is high (8, 9, and 10) than when it is low (5, 6, and 7)? There are at least 2 alternatives. First, we have defined active storage in terms of attention and rehearsal processes and echoic storage as an auditory buffer in which information is relatively unanalyzed. We have also identified active storage with attended ear and echoic storage with unattended ear. In terms of this model, the more accurate unattended-ear performance of *S*s with high digit span reflects echoic stores of larger capacity. The mean number of unattended items reported correctly per list (collapsed over report order) was calculated for *S*s of all digit-span groups. These figures, shown in Table 4, indicate values of echoic storage capacity ranging from 1.14 digits (Span 5) to 3.80 digits (Span 10). Bryden (1971) hypothesized that echoic storage was limited to 1–2 items. While this

estimate adequately describes performance for *S*s with digit spans of 5, 6, and 7, it is too low for *S*s with spans of 8, 9, and 10.

The identification of active storage with attended ear and echoic storage with unattended ear implies that no attention is directed towards the unattended ear. If, as a second alternative, we modify our working model to include the possibility that some attention is directed towards the unattended ear, a different interpretation of the more accurate unattended-ear performance of high-span *S*s arises. Consider models in which "attention" is used synonymously with "central processing capacity," "energy," and/or "mental effort" (e.g., Kahneman, 1973; Moray, 1967; Posner & Boies, 1971). In models of this type a finite central processing capacity or amount of energy is available for information processing. Any mental operations such as "encoding," "retrieval," "rehearsal," and the like, which are thought to require central processing capacity, must share from a common source. Consequently, if at any particular moment there is a large investment of central processing capacity to one mental operation (e.g., retrieval), the amount of capacity remaining for other operations (e.g., encoding and rehearsal) is reduced. If the capacity available for additional mental operations is not sufficient, impairment of performance will result.

Consider the implications which this type of conceptual analysis has for dichotic memory. All *S*s in the present experiments were instructed to "attend" (invest central processing capacity) to a 4-digit message presented to one ear. If we assume that the amount of central processing capacity required by this task is a function of the relation between length of message and digit span, *S*s with a low digit span (5 or 6) would, in order to maintain accurate performance on the task, be required to invest more processing capacity than would *S*s with a high digit span (9 or 10). More spare capacity would thus be available to high-span *S*s. Given instructions to attend to one ear, but to recall messages from both ears, an *S* might be expected to direct his spare capacity to his unattended ear. Thus in terms of the original model, unattended-ear performance would be mediated by both active and echoic storage systems. Viewed in this way, the difference in unattended-ear performance detected between *S*s with and low digit spans reflects not a diffe in echoic storage capacities, but rathe greater contribution of active storage with high digit span.

It is not possible to decide at present which of these theoretical alternatives is mo sible. While the knowledge that 79 of the variability in dichotic memo accounted for by digit span does no the theoretical issues, it does increas mental precision and it points out d for future research.

AROUSAL AND THE RANGE OF CUE UTILIZATION [1]

STEPHEN J. BACON [2]

Indiana University

The present experiment explores the effects of arousal on the range of stimulus responsiveness in terms of sensitivity and response criterion changes, the amount of attention initially focused on the stimulus, and the locus of effect of arousal. The *S*s simultaneously performed a pursuit-rotor tracking task and an auditory signal detection task under different levels of arousal, temporal locus of effect conditions, and degrees of attention being focused on the auditory cue. Results indicate that arousal narrows the range of cues processed by systematically reducing responsiveness to those aspects of the situation which initially attract a lesser degree of attentional focus. This stimulus loss under arousal represents, independently of any response criterion changes, an actual diminution in the *S*s' sensitivity. In addition, it seems that arousal mediates its effect not so much by impeding the initial sensory impression as by affecting the capacity limitations and attentional control processes operating within short-term memory.

Discussions of the effects of emotional arousal on the breadth of attention are assuming an increasingly prominent role in accounts of the experiential and behavioral consequences of arousal (Easterbrook, 1959; Korchin, 1964; Wachtel, 1967; Wine, 1971). The basic theoretical formulation is provided by Easterbrook, who suggests that the effect of emotional arousal on attention is to narrow and focus the attentional field by systematically reducing the range of cue utilization. More specifically, it is proposed that responsivity to peripheral or less relevant stimuli is diminished, while responsivity to central, immediately relevant or dominant cues is maintained, if not in fact augmented. Empirical support for the Easterbrook hypothesis may be found in the experiments of Bahrick, Fitts, and Rankin (1952), Bursill (1958), and Wachtel (1968), which have shown that, while simultaneously performing a central pursuit-meter tracking task and a peripheral visual detection task, aroused *S*s evidence considerable decrement in responding to the visual stimuli.

Perhaps the primary question that can be put to the arousal–reduced cue-utilization formulation concerns the nature of the stimulus loss. The implicit assumption being made is that this involves a reduction in the range of actual sensitivity to stimuli. The possibility exists, however, that emotionally aroused *S*s do not really experience attenuation of sensitivity to peripheral or less relevant cues, but rather are more cautious in reporting the occurrence of these stimuli. The present experiment employs a signal detection methodology (Green & Swets, 1966) to determine whether reduced responsivity under arousal to peripheral stimuli reflects an actual attenuation of sensitivity to the signal, or merely an increase in the subjective decision criterion, so that it becomes less likely that the signal will meet the stricter criterion.

It should be noted that the main thrust of the literature has been directed towards investigating the effects of arousal in reducing responsivity to peripheral cues. Easterbrook (1959), however, had postulated that the narrowing and focusing of the attentional field under arousal involves not only diminished utilization of periph-

[1] This article is based on a dissertation submitted to the University of California, Los Angeles, in partial satisfaction of the requirements for the PhD degree. The author wishes to express his appreciation to his dissertation committee chairman, William E. Broen, and to the committee members, Eliot H. Rodnick, Lowell H. Storms, James P. Thomas, and Daniel M. Wilner. The author also wishes to thank Richard H. Price for his helpful comments.

eral cues, but also the maintained, if not improved, use of central, immediately relevant cues. This suggests 2 related hypotheses to be tested: (*a*) There is a differential shift in responsivity under arousal depending upon the initial amount of attention being focused on a cue; i.e., cues which initially attract less attention should show further diminished attention under arousal, while cues which occupy the primary focus of attention should perhaps show enhanced attention under arousal. (*b*) There is a heightened sensitivity under arousal to those cues on which a high degree of attention was initially focused.

In general, the evidence that arousal increases the performance of a central task is highly inconsistent. Moreover, the type of task that has been used to measure the proposition that arousal might augment awareness of central, primary stimuli (e.g., pursuit meter) typically involves complex perceptual–motor coordination and higher order cognitive organization, and is far from testing simple stimulus responsivity. Another purpose, then, of the present investigation is to study, under arousal, differential shifts in stimulus responsivity to task cues which diverge along the dimension of amount of attention (high vs. low) being focused on them.

Finally, the research reported here is also directed towards the question of the locus of the effect of arousal on the range of stimuli that are processed. The Easterbrook (1959) hypothesis essentially asserts that the effect of arousal involves capacity limitations in information processing and the activation of attentional control mechanisms. One of the fundamental issues in information processing concerns whether such capacity limitations and attentional effects operate during the initial perceptual encoding stages of processing, or whether they operate exclusively in short-term memory store following perceptual processing (Shiffrin & Geisler, 1973). The present study, by manipulating whether the response to target stimuli is given immediately or is given after a delay, explores whether the effects of arousal on stimulus responsivity occur at the locus of perceptual or memory processes.

Method

Subjects

The *S*s were 20 students at the University of California, Los Angeles, who were paid for their participation in the experiment. They ranged in age from 19 to 25 yr. and had an average age of 21.6 yr. (*SD* = 1.82).

Apparatus and Instrumentation

The experimental task consisted of the simultaneous performance of pursuit-rotor (PR) tracking and auditory signal detection. The fluorescent light target of a Lafayette pursuit rotor, set at 40 rpm, was tracked by means of a stylus containing a photoelectric cell. A Lafayette timer clock measured time on target (TOT) to the nearest .01 sec.

The auditory signal consisted of a 1,000-cps tone generated by a Hewlett-Packard audio oscillator and monitored through a Hewlett-Packard variable attenuator. The signal was activated by a 60-msec. pulse former triggered by a Davis timer. This timer was in turn programmed by a trial stepping device which controlled whether or not the signal was to be presented. On trials in which the signal was presented, the tone was then fed through a 40-db. fixed attenuator into a Grason-Stadler noise generator and mixed there with white noise. The output from the mixer, consisting then of either a signal embedded in the noise background or just the noise background, was then fed through a 30-db. fixed attenuator into a relay system and then into a set of Sharpe stereo headphones. The purpose of the 2 fixed attenuators was to shut out switching clicks from the mechanical program equipment. The programming equipment consisted of a series of interconnected Davis timers which automatically set trial intervals (7 sec.), time of signal presentation, and intertrial intervals (5 sec.). A switch selected whether the trial timer pulsed the noise or the PR. It should be noted that when the timer triggered the relay to allow the noise (or signal plus noise) to be on for a 7-sec. trial, the PR ran continuously. In this case, the TOT counter was connected to the relay so that it marked PR tracking time only when the noise was on (i.e., only during the 7-sec. trial interval). On the other hand, in those conditions in which the trial timer pulsed the PR for 7 sec., the noise was continually fed through to the headphones. In this case, TOT could still only be scored for 7 sec., since with the PR light turned off, the photoelectric cell in the stylus was not activated. The stimulus delay timer was controlled by a device which selected the particular delay interval for the stimulus presentation. In this experiment, delays of .5, 1.0, 2.0, 6.0, and 6.5 sec. were possible.

A public address system permitted 2-way communication between the *S*'s room and the room

containing the program equipment in which E was located. A Beede electrical stimulator generated electric shocks, which were delivered via penny electrodes taped to the fingers of the S's nonpreferred hand. After each experimental condition, the Ss filled out a 20-item, modified version of Spielberger's State Anxiety Inventory (SAI; Spielberger, Gorsuch, & Lushene, 1970).

Procedure

Determination of signal intensity. At the beginning of the session, the auditory threshold for each S for a 1,000-cps, 60-msec. tone, embedded after a .5-sec. delay in a 1.0-sec. noise burst, was determined by the method of limits. Ten alternating descending and ascending runs were given. Only the last 6 runs were used in the final calculation of the threshold. The signal level was then increased 3 db. above the established threshold.

Signal detection and PR tasks. In each condition, each S was given 100 trials lasting 7 sec. each, with an intertrial interval of 5 sec. During each 7-sec. trial, the S was instructed to perform the PR tracking task while simultaneously listening through a set of headphones for the occurrence of an auditory signal embedded within a white-noise background. The S was told that on each trial the signal might or might not occur, but that if it did occur, it could do so anywhere within the trial. He was informed that this was all totally randomized, was advised of the "gambler's fallacy," and was told to make an independent judgment on each trial. When the trial was over, the S rated his subjective confidence that a signal did or did not occur on a 4-point rating scale (signal positively there, probably there, probably not there, positively not there). The S was also asked to rate from 0% to 100% how hard he was concentrating on doing the PR tracking. The program for the signal presentation was as follows: randomly, but equally, distributed over 2 blocks of 50 trials each were 13 signals presented after a delay of 1 sec. into the trial, 12 signals after 2 sec., 12 signals after 6 sec., and 13 signals after 6.5 sec. Randomly interspersed within this program were 50 noise-only trials. Half of these were randomly designated as the noise trials to be used with the early signal presentation, and half were randomly designated as the noise trials to be used with the late signal presentations. At the beginning of each session, each S received 62 practice trials. Signal previews at each of the temporal delays were presented well above threshold before each block of trials. Rest periods of 5 min. each were given after the practice trials and after each block of 50 experimental trials, and a 15-min. rest period separated the nonarousal and arousal conditions for each S.

Level of arousal conditions. Each S performed the PR – signal detection task under counterbalanced no-shock and shock conditions. The nonarousal condition consisted of a no-shock PR – signal detection task. In the arousal condition, the S was informed that E was interested in studying the effects of stress, and that shock applied to the fingers of the nonpreferred hand would be used to induce stress. The level of shock that was perceived by the S as the most painful he was willing to endure was determined. The S was told that shocks would be randomly delivered while he was performing the task, so that the longer the interval between successive shocks, the more intense the shock would be. In each block of 50 trials, 20 shocks were delivered according to a fixed random schedule. Shocks were thus delivered during both intertrial interval and experimental trials, but never at the time of signal occurrence. Actual delivered intensities varied around the predetermined level as a function of intershock interval. The Ss were asked to complete the 20-item SAI after both no-shock and shock conditions.

Focus-of-attention conditions. The Ss were randomly assigned to one of 2 groups which differed in the amount of attention that was being focused on the auditory task. Degree of focus of attention on the auditory cue was manipulated by physical and instructional means designed to pull attention either towards or away from the auditory signals. When the auditory cue was to occupy the primary focus of attention, the PR was run continuously, and the noise coming over the headphones was pulsed for 7 sec. The S was told that when the noise goes on he was to begin PR tracking and listening for the auditory signal, and as soon as the burst ended he was to stop tracking and make his signal detection and concentration ratings. Thus, the auditory channel gained further importance in that it set the stage for task performance. The S was also told that, while he was required to perform both tasks simultaneously, the more important task was the auditory signal detection task. Furthermore, if he performed above a certain criterion level on the auditory task, he could receive a bonus of $1.00. The only qualification to this was that he had to perform the PR task to a criterion, although he was assured that the criterion was fairly low. All Ss were, in fact, rewarded. Following the practice trials, S was informed that his PR performance was adequate, and he was encouraged to maintain this level. After experimental trials 25, 50, and 75, S was again assured that his PR performance was adequate, was again reminded of the importance of the auditory task, and was encouraged to concentrate on listening for the signal. When the auditory cue was to attract less attention, the manipulations favored the PR task. Thus, the auditory noise background was on continuously, and the 7-sec. trial interval was determined by the pulsing of the PR, i.e., the target was illuminated and rotated for 7 sec. and then stopped and turned off. Pursuit-rotor tracking was emphasized, and a $1.00 bonus could be received for performing PR tracking above a criterion level, provided that minimal criterion performance be maintained on the auditory detection task. Following the practice

TABLE 1

Mean Sensitivity and Mean Slope Scores for No-Shock and Shock Conditions over High and Low Degree of Focus of Attention on the Auditory Cue (HF, LF), and Immediate and Delayed Response (RI, RD) Conditions

Conditions	Sensitivity scores		Slope scores	
	No shock	Shock	No shock	Shock
HF–RI	3.02	2.63	.53	.80
HF–RD	3.32	2.61	.74	.61
LF–RI	3.13	2.30	.65	.68
LF–RD	3.61	1.60	.42	.98

trials and at the given points during the experimental sessions, S was advised that his auditory detection performance was adequate, was encouraged to maintain this level, and was reminded of the primary importance of the PR task.

Temporal locus of effect condition. Temporal factors were manipulated by varying the time between auditory signal presentation and S's report, so that the response was either immediate or delayed. The trials containing the signals presented after 6- and 6.5-sec. delay, along with their noise-only trials, were collapsed together to make up the response-immediate condition. The signal presentations occurring 1 and 2 sec. into the trial, requiring S to delay his response 5 or 6 sec., taken together with their noise-only trials, comprised the response-delayed condition.

Results

The interpretation of the effects of arousal on the range of cue utilization depends upon the effectiveness of the no-shock vs. shock manipulation in producing differential levels of arousal. Raw scores for each S on the SAI were tabulated and then translated into the appropriate percentile rank scores given from the norms on college undergraduates (Spielberger et al., 1970). An analysis of variance performed on the arousal level scores revealed the mean difference between no-shock and shock conditions (Percentile Rank 58 vs. 91) to be hightly significant, F (1, 16) = 37.08, $p < .001$. No other differences between treatment conditions were found.

The actual sensitivity of the various treatment groups to the auditory signal is expressed in terms of a linear function, Δm, representing the measure of underlying sensory capabilities, independent of response bias. Green and Swets (1966) have proposed this index of sensitivity to be used instead of d' when the assumption of equal variance in the signal and noise distributions may not be met. Values of Δm were obtained for each S based on the rating data for each of the conditions in which S participated. Cumulative conditional probabilities of hits and false alarms at each of the decision criterion points were calculated, transformed to their corresponding Z score equivalents, plotted against each other, and, by the method of least squares, they were fit with a linear function. The Z score values of the X intercepts of the linear functions served as the estimates of Δm (Green & Swets, 1966). The analysis of variance conducted on these data showed that arousal clearly diminishes sensitivity to the auditory cue, F (1, 16) = 11.32, $p < .005$. Table 1 shows the mean sensitivity scores for the focus-of-attention, temporal factors, and arousal-level treatment combinations. It can be seen that arousal produces greater sensitivity loss when the auditory cue attracts less attention, and particularly when the response to it is delayed. The planned comparisons performed to test whether arousal increases sensitivity to the auditory cue when it occupies the primary focus of attention and response is immediate or delayed, and whether arousal reduces sensitivity to the auditory cue in the low-attention condition for immediate and delayed responding, revealed that the primary effect of shock was to reduce sensitivity in the low-attention – response-delayed condition, F (1, 16) = 9.61, $p < .01$. The other comparisons fell well short of significance: F (1, 16) < 1 for the primary-attention – response-immediate condition; F (1, 16) = 1.17, $p >$ .25, for the primary-attention–response-delayed condition; and F (1, 16) = 1.65, $.25 > p > .10$, for the low-attention – response-immediate condition.

Another independent sensory parameter is the slope value of the linear function. The traditional interpretation of the slope in signal detection theory is that it equals the ratio of the variance of the noise dis-

tribution to that of the signal distribution. An analysis of variance was carried out on the slope values. A significant main effect was found for arousal level, F (1, 16) = 4.91, $p < .05$, the mean value of the slope increasing from .58 in no-shock conditions to .77 with shock. A significant interaction for arousal level and order effects, F (1, 16) = 6.60, $p < .025$, suggests that the main effect of increased slope for aroused *S*s was due primarily to those *S*s in the no-shock-first, shock-second order condition. A significant 3-way interaction of focus of attention, temporal factors, and arousal level was also obtained, F (1, 16) = 5.29, $p < .05$, and the mean slope values for each of these treatment combinations are also presented in Table 1. The planned comparisons indicated that shock significantly increases the slope value only in the low-attention – response-delayed condition, F (1, 16) = 7.66, $p < .025$.

Typically, changes in the ratio of the variances of the noise to the signal distribution have been taken to indicate changes in the way *S* is processing information about signal parameters. However, while it is of interest to know in the present experiment that not only sensitivity changes but also underlying information-processing strategy changes occur under arousal, no additionally meaningful psychological information can be ascertained from the slope statistic concerning the locus of arousal's effect. There will, therefore, be no further discussion of the slope data.

Another measure which further describes *S*'s behavior on the auditory detection task is the hit rate *Z* score, $Z(y|SN)$, where y = yes, signal was present, and SN = signal was added to noise background, which provides fairly direct estimates of shifts in response criterion when sensitivity values do not differ. In addition, it is the hit rate scores in this study which are most closely analogous to the perceptual performance measures of previous central-tracking – peripheral-light studies. Table 2 shows the mean hit rate *Z* scores at each of the cumulative subjective criterion

TABLE 2

Mean Hit Rate *Z* Scores at Each Criterion Point for No-Shock and Shock Conditions over High and Low Degree of Focus of Attention on the Auditory Cue (HF, LF) and Immediate and Delayed Response (RI, RD) Conditions

Conditions	No shock			Shock		
	Strict	Moderate	Lax	Strict	Moderate	Lax
HF–RI	−.531	.512	1.296	−.260	.592	1.320
HF–RD	−.348	.690	1.661	−.179	.756	1.487
LF–RI	−.305	.573	1.252	−.491	.371	.848
LF–RD	−.229	.546	.925	−.689	.629	.962

points as a function of focus of attention, temporal factors, and arousal level. The analysis of variance and the planned comparisons performed on the overall mean hit rate *Z* score, $\bar{Z}(y|SN)$ revealed no significant differences between treatment conditions. This finding is somewhat surprising in that one might expect that, given the observed reduction in sensitivity under shock, an overall lowering of the average number of hits should follow. An explanation of this finding, which seems to be supported by reference to Table 2, is that treatment manipulations had opposing effects at different criterion points, thus leaving the overall average number of hits unchanged.

Particularly noteworthy in Table 2 are the hit rate *Z* score data associated with the most stringent criterion point, in that the previous central-tracking – peripheral-light experiments, which required *S* to switch off the peripheral light when he saw it was on and recorded the amount of time the light remained on, were probably dealing with a criterion range covered by the most stringent criterion point in the present investigation. Table 2 shows that, at the most stringent criterion level, under arousal there is a moderate increase in hit rate when the auditory cue occupies the primary focus of attention, but a marked decrease in the hit rate when the auditory cue attracts less attention, most dramatically when response is delayed.

Time on target per trial performance on the PR was also evaluated by an analysis

of variance. The results that merit consideration here are the significant Temporal Factor × Arousal Level interaction, $F(1, 16) = 4.99$, $p < .05$, which indicates that only when the response to the auditory cue is delayed did shock produce decrement in PR performance. The planned comparisons revealed that shock produced significantly lower PR scores only in the low attention to the auditory cue (hence centered attention on the PR)–response-delayed condition, $F(1, 16) = 8.42$, $p < .025$.

Discussion

The results of the present experiment support Easterbrook's (1959) hypothesis that the effect of arousal is to reduce the range of cue utilization, and the results are also consistent with the conclusions of Bahrick et al. (1952), Bursill (1958), and Wachtel (1968) that emotional arousal decreases responsiveness to peripheral stimuli. More important, the data indicate that the stimulus loss under arousal involves a diminution in *S*'s sensitivity, independently of any response criterion changes. Moreover, arousal seems to have differential effects depending upon the degree of attention the stimuli attract, sensitivity loss systematically occurring to those cues which initially attract less attention. On the other hand, the present study offers no support for the suggestion that arousal might augment sensitivity to cues which occupy the primary focus of attention. One must note, however, that the PR is such a demanding and compelling task that, despite the manipulations designed to focus attention on the auditory task, it is quite likely that the auditory cue never achieved attentional centrality. Thus the present study may not have provided the optimal conditions for a central enhancement effect to emerge.

Some additional evidence emerges from this study which may be viewed as an extension of the findings that arousal reduces the range of cue utilization. A significant decrement in both PR performance and sensitivity to the auditory cue was obtained under arousal in the low-attention – response-delayed condition. This seems to suggest that when *S* is required to perform the PR task while also retaining the memory trace of the auditory signal, arousal reduces *S*'s ability to attend to both tasks simultaneously. This provides support for the notion that arousal reduces the number of cues *S* can handle at [a] time, the capacity, in Korchin's (1964) terms, for dual activity. In addition, these results indicate that arousal introduces further capacity limitations within the short-term memory system.

The response-immediate and response-delayed manipulations in the present study were directed at determining the locus of effect of arousal in reducing the range of stimuli that are processed. The response-immediate condition was designed to test the effects of arousal on perception. It is realized that response delays of .5 and 1.0 sec. were involved here and thus memory mechanisms may be implicated. Nonetheless, if arousal affects perception of external stimuli by attenuating signals arriving over sensory channels, this would surely have resulted in a sensitivity loss in the response-immediate condition. While a trend towards diminished sensitivity was found in the low-attention – response-immediate – shock condition, it did not attain statistical significance. Thus, there is little evidence from the present investigation that arousal acts effectively to impede perception of stimulus input. On the other hand, the response-delayed condition, designed to evaluate the effects of arousal on memory processes, did show reduced sensitivity to the auditory cue under low-attention – shock conditions. This suggests that arousal narrows the range of stimuli that are processed by impairing the memory traces of those signals which initially attract less attention. Arousal may exert its effect in this condition by both overloading the system and thereby exceeding the capacity limitations of short-term storage, and by interfering with the attentional control processes, such as rehearsal, that aid in maintaining information in short-term memory. Within this context, it is interesting to note that the differential effects of the focus-of-attention manipulations in the present experiment become evident only within memory and under the capacity limitations imposed by arousal. The results and conclusions presented here are consistent with those advanced by Shiffrin and Geisler (1973), that attentional effects and capacity limitations operate solely within short-term memory storage following perceptual processing.

ARTICULATORY INTERFERENCE AND THE MOW... HETEROPHONE EFFECT[1]

JOHN L. BRADSHAW[2] AND NORMAN C. NETTLETON

Monash University, Clayton, Victoria, Australia

When *S*s are required to utter rapidly a sequence of visually presented which are closely similar in spelling, but not in pronunciation, such a DOWN or HOME–SOME, hesitations and confusions may result. These were found to be less apparent when the same items are so interleav members of "heterophone" pairs such as the above are no longer adja each other. It was shown that this heterophone effect was unlikely to d on the *S*s scanning ahead or perceiving later words in peripheral vision phenomenon was studied further in terms of the times for initiating and pleting the articulation of items either separately or in pairs. By varyi contingencies of presentation and utterance of paired items (hetero and neutrals), it was found that a pronunciation set could be establis cause subsequent interference. However, overt articulation was nec for this, not merely covert reading or memorizing, and the effect was fested in the time taken to initiate articulation, not its duration. The fin were discussed within the context of word recognition, pronunciation set grapheme–phoneme recoding.

A phenomenon in English orthography is the existence of large groups of words such as MOWN–DOWN, QUART–PART, HORSE–WORSE, HOME–SOME, and TOW–COW. Such heterophone pairs share largely the same spelling, but with some considerable pronunciation differences. When we encounter any one such word in isolation, there is usually little difficulty in pronunciation. When a number are juxtaposed, the speaker may become confused.

A number of experiments are reported where this phenomenon is investigated. The findings are later considered within the context of phonemic recoding of visually presented stimuli ("indirect access" theories, Smith, 1971), Morton's logogen theory (Morton, 1969), sensory and motor "buffer" stores in reading, and the role of peripheral vision in reading.

Experiment I

The aim of this experiment was to examine the possibility that *S*s may have more difficulty in correctly pronouncing a sequence of words where the members of heterophone pairs such as ROOT–FOOT, RAID–SAID, BOWL–FOWL, etc., are adjacent to each other, than where they are separated from each other by single members of other heterophone pairs.

Method

Material. Dictionaries were searched to obtain 48 pairs of heterophone items. The words varied from 3 to 8 letters in length, and all except 9 pairs were single syllables, the remainder being bisyllabic. The items were arranged in 4 vertically organized lists. In the first list the 2 members of a pair were always one immediately above the other, i.e., there were no intervening items (List 0). In the next, the same words were arranged in an interleaved form, so that there was always one item between the 2 members of a heterophone pair—these members themselves serving to separate other heterophone pairs—thus: HOME–NORTH–SOME–WORTH–SOUGHT–WEAR–DROUGHT–FEAR, etc. There was therefore one intervening item (List 1). In the third list, the same words were arranged so that there were 3 intervening items (List 3), thus: HOME–NORTH–SOUGHT–WEAR–SOME–WORTH–DROUGHT–FEAR, etc. Finally, in the last list (List 7), the words were so interleaved that there were always 7 intervening items, e.g., HOME–NORTH–SOUGHT–WEAR–ROLL–WEIGHT–ROOT–THOUGH–SOME–WORTH–DROUGHT, etc.

Procedure. These 4 lists can be arranged in 24 possible orders. Twelve of these were selected which permitted 3 different complementary designs of the Latin square type. The 12 *S*s were all required to read aloud each of the 4 lists twice, i.e., in accordance

the particular specified sequence and also in the ...se of that sequence, thus: 3, 0, 1, 7, 7, 1, 0, 3. Th... were timed with a stopwatch while reading, a... were encouraged to read as fast as possible, ke...ing mistakes of pronunciation and hesitations to... minimum. They were instructed to continue re...ng if they did make a mistake, and not to go b... and correct it. The *S*s, 4 males and 8 females, we... staff or postgraduate student members of the de...artment of psychology of Monash University.

...esults and Discussion

The means of the reading times for the 4 ...sts, across the 12 *S*s, were: List 0, 41.5 ...ec.; List 1, 38.3 sec.; List 3, 36.7 sec.; ...nd List 7, 37.0 sec. A 2-way analysis of variance (within *S*s) showed a significant difference between the lists, $F\ (3, 33) = 34.1$, $p < .001$. In fact List 0 was the longest for all 12 *S*s, without exception, and with only one exception, List 1 took a longer time to read than List 3.

It seems therefore that when *S*s are ...uired to read lists of such heterophone items, as fast as possible consistent with a minimum of mistakes, there is considerable interference both when the items are adjacent, and even, although to a lesser extent, when they are interleaved so that they are each separated by a "neutral" item.

A number of possible explanations will be discussed later. One possibility, otherwise of little theoretical interest, is simply that *S*s were either scanning ahead or, what comes to the same thing, able to see the next member of the pair in peripheral vision. This might have caused interference in the case of adjacent heterophones.

EXPERIMENT II

There is perhaps a fairly simple test to see whether a word beyond the one currently being processed can interfere with the current one. In English there are a number of heteronyms, such as LEAD (rhyming with either BEAD or DEAD, depending upon meaning), ROW, SOW, and BOW (rhyming with either HOW or LOW), TEAR (rhyming with either PEAR or FEAR), WIND (TINDER or BINDER), and WOUND (...OUNDED or BOUNDED). If *S* encounters ...EAD followed by BEAD (or DEAD) in a list, is he more likely to pronounce it in rhyming fashion? Lists were constructed, containing filler and critical items such as the above, to see whether scanning ahead (or peripheral vision) tends to influence the pronunciation of ambiguous heteronyms.

Method

Material. Two vertical lists of single words were constructed. Both contained identical filler items—rhyming pairs such as SINK–DRINK, STONE–BONE, etc., interspersed with heterophone pairs such as OUR–FOUR, NEVER LEVER, etc. In this way it was hoped to avoid the establishment of a set or expectancy for complete or partial rhyming. At certain positions 6 critical items were located. In one list these were BOW–COW, TEAR–FEAR, LEAD–BEAD, ROW–LOW, WIND–BINDER, WOUND–BOUNDED. In corresponding positions in the other list were found BOW–TOW, TEAR PEAR, LEAD–DEAD, ROW–HOW, WIND–TINDER, WOUND-WOUNDED.

Procedure. Each of the 9 *S*s, 3 males and 6 females, was required to read the 2 lists aloud, as though he was being timed. In fact it was noted whether or not the *S*s pronounced the critical, ambiguous heteronym item to rhyme with the following word. The *S*s were given the 2 lists one before and one after another experiment lasting approximately 1 hr. Half of the *S*s were given one of the 2 lists first, and the others were given the other list first.

Results

The critical items were scored as rhyming or not rhyming. If *S* pronounced either the first or second word of a pair incorrectly, this was scored as an error. The total number of rhymes, nonrhymes, and errors are shown for each list in Table 1, as are the totals over the 2 lists. Table 2 shows the number of times *S*s pronounced the given test word the same or a different way in each list. Table 3 shows how each test word was pronounced, if pronounced correctly, on a total of 18 presentations.

TABLE 1

TOTAL NUMBER OF RHYMES, NONRHYMES, AND ERRORS FOR EACH LIST, OVER NINE SUBJECTS

Pronunciation	First list	Second list	Total
Rhymed	29	22	51
Not rhymed	21	31	52
Errors	4	1	5

TABLE 2

Total Number of Times Subjects Pronounced a Word the Same Way in Both Lists

Test word	Same	Different	Errors
BOW	6	2	1
TEAR	8	1	0
LEAD	6	2	1
ROW	6	2	1
WIND	8	1	0
WOUND	6	1	2

Discussion

The results shown in Table 1 suggest that scanning ahead did not play an important part in the reading of these lists. Overall, *S*s were equally likely to rhyme or not rhyme the critical items. However, this may merely be due to a strong overriding tendency for *S*s to pronounce the ambiguous test word in one particular way. Table 2 shows that this was the case—the test words were pronounced the same way in both lists on 40 occasions and differently on 9. This does not mean that *S*s agreed on their preferred pronunciation. Table 3 shows that only 2 words—TEAR and WIND—were pronounced in the same way by a majority of the *S*s.

If scanning ahead does occur it does not appear to have sufficient influence to override *S*s' tendency to pronounce a given test word in their own preferred way. It therefore seems unlikely that the heterophone effect in Experiment I was due to *S*s' scanning ahead, or perceiving a later word in peripheral vision.

This experiment could be repeated with the ambiguous words (BOW, TEAR, LEAD, etc.) occurring after instead of before the words with which they could be rhymed (COW–BOW, TOW–BOW, etc.). This would show whether the first word encountered influences the second. However, there is evidence for this in the present data, because all 5 errors were due to *S*s' choosing a particular pronunciation of the first word and then making a nonword of the second word by rhyming it with the first, e.g. pronouncing the pair BOW and TOW as if to rhyme with COW. Thus the heterophone effect in Experiment I may be the influence of an earlier word on a later one, rather than the influence of one seen below in peripheral vision on the one currently being processed.

TABLE 3

Pronunciation and Errors for Each Test Word for the Two Lists Combined, over Nine Subjects

Test word	Pronounced as in:	No. of times	Errors
BOW	Tow	8	1
	Cow	9	
TEAR	Pear	15	0
	Fear	3	
LEAD	Dead	9	1
	Bead	8	
ROW	How	8	1
	Low	9	
WIND	Tinder	13	0
	Binder	5	
WOUND	Wounded	9	2
	Bounded	7	

Experiment III

In the first experiment, it was found that it took longer to read material correctly when the members of heterophone pairs were adjacent than when they were separated by intervening items. If only one member of a pair is articulated, the first being merely observed or subvocally identified, does the heterophone effect persist? If it does, it would imply that overt articulation may not be necessary to cause interference. Successive pairs of words were therefore presented on a computer-controlled oscilloscope, *S*s being required to observe the first and name the second, vocal initiation times being obtained.

Method

Material. Because of equipment and other constraints, words of only 4 letters were employed. A total of 25 heterophone pairs were obtained and a PDP-8/S computer was programmed to present them on a Tektronix RM 503 oscilloscope screen. Each item consisted of a pair of words, either a heterophone or a neutral pair. The latter consisted of one from each of 2 otherwise unrelated heterophone pairs. Thus the 2 heterophone pairs WART–PART and HIVE–GIVE generated the 2 neutral pairs WART–GIVE and HIVE–PART. Heterophone and neutral pairs were pseudorandomly intermingled, with certain constraints to avoid uneven sequencing effects. Every word appeared both at the beginning and end of a heterophone and a neutral pair, i.e., it

occurred somewhere in each of the 4 possible positions. Thus the 25 heterophone pairs generated 50 heterophone items, taking sequencing of members into account. There were also, correspondingly, 50 neutral items.

Procedure. The *S*s sat in front of the oscilloscope screen, at a distance of 40 cm., viewing it through a tachistoscope-type viewing hood. On each trial the *E* said "Ready" and *S* pressed a hand-held button. The first words then appeared in a faintly luminous target area for a total of 237 msec. In fact it was "written up" 3 times, each left-to-right scan taking 79 msec. After a blank interstimulus interval of 193 msec., the second word appeared in the same location, also for 237 msec. The *S*s were required to note the first word but to make no verbal response. They shouted out the second word as soon as they could, closing a voice-operated switch which stopped a timing routine begun at the offset of the second word. The initiation time thus obtained was printed out on the teletype. There were 8 new *S*s, 5 females and 3 males. Any stutters or articulatory blocks were excluded from analysis. However, over all *S*s, only 5 neutral and 7 heterophone items were so excluded.

Results and Discussion

The average time to initiate a verbal response (naming), after the offset of the second word (duration of 237 msec.) was 286 msec. for heterophone pairs and 288 msec. for neutrals. Thus there was a minimal and nonsignificant difference in a direction opposite to the one predicted, only 3 of the 8 *S*s producing longer vocal initiation times for heterophone pairs, $t\ (7) = .3$, $p > .8$. It would seem that under the conditions of this experiment, the second item of a heterophone pair can be initiated as readily as the second item of a neutral pair. Any slight facilitation for heterophone pairs may perhaps stem from easier decoding, resulting from the shared letters appearing spatially superimposed.

Experiment IV

When *S* covertly identified but did not articulate the first member of a pair of words, the expected heterophone effect failed to materialize in the initiation times for articulating the second word. Can it be made to reappear, under the conditions of separate paired presentations when *S* also articulates the first word and thus triggers the presentation of the second? In this experiment not only initiation times but also duration times were obtained for the articulation of the second word.

Method

Material and subjects. The same material and sequence were employed as in Experiment III. However, a totally new group of 8 volunteer *S*s, 4 males and 4 females who were entirely naive as to the material being used, was obtained.

Apparatus and procedure. The computer was programmed to present the first word of a pair for 237 msec. when *S* pressed the hand-held "ready" button. Exactly 388 msec. after *S* started to name the first word, the second word appeared, also for 237 msec. The computer and auxiliary equipment were programmed to time both initiation (after offset of the second word) and duration of *S*'s vocalization of the second word. The long interval (388 msec.) was chosen to insure that vocalization of the first word was completed before the second word went off and to insure that there was a gap between the 2 articulations. This permitted the timing of the parameters relating to the second word alone. Measurement of the duration of the second word was achieved by the construction of a special device. Since there are silent periods within articulated words, a voice-operated switch is not kept closed until the offset of the last voiced period, but tends to oscillate between its open and closed positions as it attempts to follow the intensity changes in the articulation. The voice-operated switch was therefore used to start a chronoscope and a specially constructed timer, which was reset each time it received a pulse from the voice-operated relay. If it did not receive a pulse this timer timed out after a preset interval (100 msec. in this experiment) and stopped the chronoscope, which thus gave the duration of the word plus 100 msec. The computer was programmed to reset the chronoscope and the timer at the commencement of each trial, and to hold them in this mode until the second word had been displayed. The initiation time was determined as before by a timing loop in the computer and printed out on the teletype. The *E* monitored *S* and the equipment and noted any trials on which a preliminary stutter was timed instead of the whole word. Over all *S*s, 13 neutral items and 14 heterophones were excluded from the analysis of initiation times, and 22 neutral items and 19 heterophones from the analysis of duration times. Some initial technical problems led to the exclusion of the extra duration times.

Results and Discussion

This time, all 8 *S*s showed faster initiation times to the second word with heterophone pairs than with neutral pairs, $t\ (7) = 4.9$, $p < .002$, again in the direction contrary to that predicted. The mean for heterophones was 273 msec. (after stimulus

offset), and for neutrals 289 msec. For some reason the trend observed in Experiment III became highly significant, although it should be noted that *S*s now had to articulate the first word. No difference in duration times was observed between heterophones (243 msec.) and neutrals (245 msec.), 4 *S*s showing very small differences in one direction, and 4 in the other. Obviously any effects operate upon the setting up of articulatory programs, not upon their operation.

The continued absence of the expected heterophone effect could possibly be due to the fact that the 2 words, although spatially superimposed, were temporally separated, as were the 2 verbal responses. It is important to see whether the strong effect obtained in serial list reading can be reproduced in the discrete situation of paired presentations.

Experiment V

In this experiment both words were presented in immediate succession, one above the other. The *S*s were required to articulate both together, and as before both initiation and duration times were measured. It was hoped that this way the predicted heterophone effect would reappear.

Method

Procedure. Using the same stimuli as before, and a new group of 8 naive *S*s, the 2 words were presented in immediate succession. The first word was written up twice and thus appeared for 158 msec. It was immediately followed by the second word, again for 158 msec., but this time directly below the first one, to avoid masking and facilitative effects which could result from superposition. The *S*s were required to name both words as fast as possible, both initiation and duration times being measured as before. In order to insure that the chronoscope measuring duration times was not stopped by a short pause between the 2 words, the timer was set to time out after 400 msec. The chronoscope thus gave the duration time for the 2 words plus 400 msec., a constant subsequently subtracted from the data.

Results and Discussion

In this experiment, with the initiation times the expected heterophone effect reappeared, the heterophones being on average 26 msec. longer than the neutrals, $t\ (7) = 2.02, p < .05$, one-tailed. Only one of the 8 *S*s gave a contrary result. The mean for heterophones was 276 msec., and for neutrals 250 msec. With the duration times, there was also an 11-msec. decrement with heterophones (701 msec.) as compared with neutrals (690 msec.), though this failed to reach significance, $t\ (7) = 1.7, p > .1$, being found only with 5 of the 8 *S*s. Thus the expected heterophone effect can be made to reappear with discrete presentations of paired stimuli. However, it is much weaker than that originally found with the continuous list-reading material. In Experiment I there was a difference of over 4.5 sec. between lists at the 2 extremes, each being composed of 48 pairs of heterophones and 48 neutrals. Thus there was in effect a difference of over 90 msec. per word pair. If the initiation and duration differences from Experiment V are added, there is a difference of little more than 38 msec. per pair. Consequently, it seems that much of the original heterophone effect stemmed from the continuous forced pace of articulation, not present with discrete presentations.

Experiment VI

Experiment V established some of the conditions necessary to demonstrate the heterophone effect with single word pairs. Whether actual articulation of both words is necessary for interference to occur is still uncertain, although this was the starting point for Experiment III. Experiment V was therefore repeated without articulation of the first word.

Method

Procedure. Exactly the same *S*s and procedure were used as in Experiment V except that instead of articulating both words, *S*s were required to note the first word, articulate the second as quickly as possible, and then, after the teletype had finished printing out the response time, tell *E* what the first word had been. There was an interval of approximately 3 sec. between presentation of the first word and *S*'s being free to report it. This depended on how long *S* took to respond with the second word. As before, both initiation and duration times were measured for the second word presented, i.e., the

first word called out by *S*. The timer controlling the chronoscope was set to 100 msec., and this value was subtracted from the chronoscope readings.

Results and Discussion

While the heterophones (508 msec.) still gave rise to longer initiation times than the neutrals (493 msec.), the difference (15 msec.) was smaller and 3 *S*s gave results in the opposite direction, making the effect nonsignificant. The duration times were nonsignificantly longer for the neutrals (349 msec.) than for the heterophones (342 msec.), $t = 1.7$, $p > .1$. The heterophone effect seems therefore to require *S* to articulate both members of the pair.

General Discussion

When people are required to read aloud a continuous list of material consisting of paired heterophones such as WART–PART, etc. (Experiment I), they find it more difficult than when the heterophone members are separated by "neutral" items (in reality, other heterophone members similarly separated). Some considerable residual difficulty persists even when there is one intervening item between successive members of a heterophone pair. The effect can also be found with discretely presented pairs of stimuli (Experiment V), when it is seen to depend largely upon the time taken to initiate the appropriate verbal response rather than the duration of that response. However, the cumulative, interactive effect of load with a continuous list appears important, the effect being very much weaker in the discrete mode of presentation (Experiment V), and nonexistent when the second word is presented only after *S* articulates the first (Experiment IV).

The effect demands the articulation of each item, and is not apparent in the initiation time for the second item when *S* merely notes the first item (Experiment III) or temporarily stores it for recall after pronouncing the second (Experiment VI). Moreover, the greater effect in the continuous list-reading task cannot be due solely to scanning ahead or to the employment of peripheral vision, since the pronunciation of ambiguous heteronyms such as LEAD, WIND, etc., is apparently not influenced by subsequent words such as BEAD–DEAD, TINDER–BINDER (Experiment II). Kolers and Lewis (1972) review the role of peripheral vision and eye movements in vision. They conclude that peripheral vision may indeed be more than simply a ranging instrument guiding the fovea. Some content analysis seems possible from input presented through several degrees of visual angle. However, this is successful only when all the information, foveal and peripheral, is part of a single word, and not 2 or more words distributed between the 2 areas. Kolers and Lewis conclude that "simultaneous processing of different linguistic units from center and periphery is not a strategy that the rapid reader could profitably engage in [p. 123]."

Failure to produce a heterophone effect in either of the 2 experiments where *S* merely "noted" or "stored" the first item (Experiments III and VI) seems to go against Morton's (1969) logogen theory. This states that any act of storage or identification of a word calls up a motor (articulatory) program, which would interfere with any other such item being processed. However, it is possible that in both these experiments the material persisted at a satisfactory and noninterfering level in some form of sensory "buffer" store.

It is debatable whether phonological recoding inevitably precedes or accompanies further processing—the indirect access theory (criticized by Smith, 1971). The latter probably owes its origins to work on short-term memory and acoustic confusions. (Baddeley, 1966; Conrad, 1963, 1964). However, these effects may well be memory and load dependent; certainly in such studies ample time was always available, and the stimuli were frequently single letters. A similar comment may be made with respect to the visual buffer store studies of Posner, Boies, Eichelman, and Taylor (1969) and Sternberg (1969). Rubenstein (Rubenstein, Garfield, & Millikan, 1970; Rubenstein, Lewis, & Rubenstein, 1971) found that homophonic nonsense words (BRANE, SPAID, etc.) require longer decision times as to whether they are real words than nonhomophonic nonsense words (BRATE, SPOID), perhaps because the former excite more false matches requiring rejection. Other support for the inevitability of phonological recoding comes from Dick (1971)—naming precedes categorization, from Klapp (1971)—implicit speech cannot be inhibited even in a same–different matching task where it is not required, and from Dalrymple-Alford (1972)—it is difficult to suppress the reading responses in a Stroop task.

On the other hand, proponents of the direct access theory (cf. Bower, 1970; Kolers, 1970; Smith, 1971) would claim that phonological representation is not a necessary part of the

recognition of a visually presented word, perhaps being superfluous in the case of practiced readers, familiar material, and high reading speeds.

From the studies reported here, it does seem that actual and overt articulation of both items is necessary to produce the interfering effect with heterophones. Thus an articulatory set may be briefly established, which is briefly linked to a particular configuration of letters—a "grapheme-phoneme correspondence" (Gibson, Pick, Osser, & Hammond, 1962).

DIFFERENTIAL CLASSICAL CONDITIONING OF POSITIVE AND NEGATIVE SKIN POTENTIALS

KATHLEEN GLAUS[1] AND HARRY KOTSES

Ohio University

The positive and negative components of the skin potential response (SPR) were investigated in a differential classical conditioning paradigm employing a 10-sec. interstimulus interval (ISI). The *S*s were 30 undergraduate females. Analyses of variance indicated that conditioned effects, measured in terms of response frequency, were present in both SPR components, and that these occurred in early as well as late portions of the ISI. Intrasubject response comparisons revealed that *S*s exhibited a predominant response polarity and displayed both conditioned effects and orienting behavior in terms of that polarity. Procedural considerations in SPR conditioning were also discussed.

In classical conditioning of electrodermal responses, a great deal of attention has been devoted to skin resistance while only a few studies have been concerned with skin potential. Additionally, the work dealing with the latter response has largely been characterized by a lack of conditioned effects, possibly resulting from inappropriate control and scoring procedures. Loveless and Thetford (1966) reported a failure to observe skin potential response (SPR) conditioning. However, their design, incorporating test trials interspersed among conditioning trials in a single group, may have precluded a meaningful assessment of conditioned effects. Similarly, Yamazaki, Watanabe, and Niimi (1969) employed test trials during a series of simultaneous conditioning trials and evaluated conditioning in terms of the relative amplitudes of positive and negative SPR components on test trials. They concluded that since the negative responses increased across test trials while the positive component responses decreased, the negative component was more likely to reflect a conditioned effect. While interesting, this interpretation is difficult to sustain since the design employed lacks an appropriate conditioning control (Rescorla, 1967). Several studies have adequately dealt with the control problem but have failed to produce unequivocal results. Kotses (1969), in a study employing unpaired control groups where simultaneous recordings of skin potential and skin resistance were made, found no evidence of conditioning in either SPR component, although the skin resistance response (SRR) showed a strong conditioned effect. In this case, SPR conditioning may have been obscured by the independent groups design, by the scoring system employed,[2] or possibly by the fact that pairing effects were evaluated in terms of response amplitude. Finally, successful conditioning of the positive potential, in terms of response magnitude, was reported by Shmavonian, Miller, and Cohen (1968), who utilized a differential conditioning paradigm in a study designed to examine age and sex differences in autonomic conditioning. Differential responding was demonstrated only in the young *S*s (ages 17–25), and no evidence for negative potential conditioning was obtained. The lack of more general conditioned effects in this study may have been due to attenuated overall responsiveness resulting from the presentation of a series of adaptation trials prior to the acquisition session.

The predominant use of the SRR and subsequent neglect of the SPR in electrodermal conditioning have been due largely

[1] Requests for reprints should be sent to Kathleen Glaus, Department of Psychology, Ohio University, Athens, Ohio 45701.

[2] Negative component amplitudes were scored as the sum of all negative potentials following onset of the conditioned stimulus. These were measured between negative response onset and peak negative level. Positive component amplitudes were measured between peak negative and peak positive levels. Only one positive deflection but as many as 2 negative deflections were recorded per trial.

to problems encountered in the evaluation and interpretation of the positive, negative, and multiphasic potential wave forms (Holmquest & Edelberg, 1964). While the SRR does offer certain advantages in terms of simplified scoring and interpretation, these may be outweighed by distortions resulting simply from the passage of an electric current through the skin which may act in some way to alter skin structures. The SPR is inherently free of this source of artifact and its complex wave forms may offer a further advantage in yielding ad-ditional information not available in the uniphasic SRR (Edelberg, 1967). With regard to the latter, a number of investigators have suggested that the component wave forms of the SPR may be differentially sensitive to conditioning (Shmavonian et al., 1968; Yamazaki et al., 1969) and to various perceptual and cognitive factors of psychological interest (Burstein, Fenz, Bergeron, & Epstein, 1965; Forbes, 1936; Forbes & Bolles, 1936; Hupka & Levinger, 1967; Raskin, Kotses, & Bever, 1969). Thus, of the 2 electrodermal responses, the SPR is potentially a less ambiguous measure than the SRR and one which may yield additional information concerning complex variables in classical conditioning.

The purpose of the present study was twofold. First, an attempt was made to determine which components of the SPR are modified in classical conditioning. Thus the relative effect of conditioning on the frequency of positive and negative potentials was examined. Second, the differential effect of conditioning on long and short latency responses was assessed. This aspect was of interest in light of inconsistent evidence from SRR studies dealing with the temporal locus of conditioned effects in a long interstimulus interval (ISI). While it is a general finding that responses appearing late in a long ISI are reliably affected by pairing (Gale & Ax, 1968; Gale & Stern, 1967; Leonard & Winokur, 1963; McDonald & Johnson, 1965; Prokasy & Ebel, 1967; Stewart, Stern, Winokur, & Fredman, 1961), some studies have failed to demonstrate conditioned effects for early responses (Leonard & Winokur, 1963; McDonald & Johnson, 1965; Stewart et a[illegible] 1961). This problem appeared to be [illegible] some significance with respect to SPRs be[illegible] cause of the possibility that potentials [illegible] different polarity would be associated wi[illegible] early and late portions of the ISI. Finall[illegible] an attempt was made in the present stu[illegible] to avoid certain of the problems obser[illegible] in previous SPR conditioning work. Sp[illegible] ically, a differential conditioning paradi[illegible] not preceded by an adaptation session w[illegible] employed to provide a precise intrasubj[illegible] control for sensitization and to elimin[illegible] the uncertain effects of prior habitua[illegible] Additionally, response frequencies, ra[illegible] than magnitude measures, were obtai[illegible]d since the former would seemingly be l[illegible] sensitive to artifact introduced by int[illegible] actions between subsequent positive a[illegible] negative wave forms (Lykken, Miller, & Strahan, 1968).

Method

Subjects. Thirty female undergraduate psychology students, ranging in age from 18 to 23 [illegible] served as *Ss*. Subjects were volunteers and received extra course credit for participation.

Apparatus. Skin potentials were picked up by 2 Beckman Ag–AgCl electrodes having a diameter of 1.5 cm., amplified by a Grass model 7P1B low-level dc preamplifier, and displayed on one channel of a Grass model 7B polygraph operated at a paper speed of 25 mm/sec. The electrodes were attached to the skin with Beckman electrode collars, and Beckman electrode paste served as the electrolyte. Lights serving as conditioned stimuli (CSs) consisted of 2 7.5-w. white lights having a duration of 10 sec. These were mounted side by side in 5 × 5 × 10 cm. individual metal compartments which were completely enclosed with the exception of the side facing *S*. This side was covered by 2 5 × 5 cm. metal slides whose centers consisted of an open circle 4.5 cm. in diameter. Red and yellow sheets of translucent plastic were placed over the circles to diffuse the light and provide chromatic differences between the 2 signals. These stimuli were presented at eye level approximately 5 ft. in front of the seated *S*. The unconditioned stimulus, a 500-msec. 112-db. white noise, was produced by a Grason-Stadler model 455B white noise generator, amplified by a locally constructed audio amplifier and presented to *S* via Koss PRO-4 headphones. Onset and duration of both visual and auditory stimuli were controlled by BRS-Foringer solid-state control equipment. During recording, *S* was seated in a comfortable armchair located in a 3 × 5 m. room with an ambient sound level of 45 db. All sound

levels were measured with a General Radio sound-level meter, model 1565-A.

Procedure. A differential delay classical conditioning paradigm with a 10-sec. ISI was employed. Twenty CS+ and 20 CS− trials, wherein CS color was counterbalanced across *S*s, were presented in random order with the stipulation that no more than 3 trials of either type occur in succession. Intertrial intervals varied between 40 and 80 sec. around a mean of 60 sec.

Upon arrival at the laboratory, *S* was escorted into the experimental room where *E* applied the electrodes. Electrode sites were cleaned with a 70% solution of ethanol, and a Kimwipe was used to abrade the skin under the inactive electrode. The active electrode was positioned over the thenar eminence of the left hand and the reference was attached to the volar surface of the left forearm approximately 8 cm. below the elbow. A ground electrode was attached to the dorsal surface of the right hand. Standard instructions read to *S* stressed the importance of refraining from unnecessary movement and remaining awake and alert during the session. Following this, *E* positioned the headphones on *S* and entered the recording room to initiate the session.

Scoring of skin potentials. The ISI was divided into 2 scoring intervals, .4–5.0 sec. and 5.1–10.0 sec. after CS onset, and all skin potentials were classified as either first- or second-interval responses according to their onset latencies. Since large changes in the tonic skin potential level were rarely observed during the ISI, the base level at stimulus onset on each trial was employed as a reference from which the polarity of subsequent phasic responses was determined. Thus, uniphasic potentials were scored as negative or positive responses, respectively, according to whether pen deflection was in the direction of increasing or decreasing negativity relative to the reference level. When 2 or more responses occurred in succession (diphasic and polyphasic responses), additional criteria were employed. Specifically, if all phasic responses were in the region of increased negativity relative to the reference level, successive negative-going deflections were scored as negative responses while positive-going movements of the pen were judged as returns to base level. Similarly, for phasic responses in the region of decreased negativity, successive positive-going deflections were scored as positive responses and negative-going movements of the pen were seen as returns to base level. In cases where the peak-to-peak excursion of the pen crossed the reference level, successive peaks were scored, as were uniphasic responses, according to the polarity of the region in which each occurred.

Only deflections representing a .5-mv. or greater change in potential and having a slope of at least 10° were counted as responses. Artifact due to movement or to faulty electrical contact was eliminated on the basis of extremely high slopes (approaching 90°) and irregular wave shape.

The frequency measures obtained included all criterion responses occurring on each trial since, at present, no strong theoretical basis exists for restricting attention to any one response and since the total frequencies reflected the relative degree of positive and negative skin potential activity.

Results

Conditioned effects in positive and negative potentials were observed in both portions of the ISI. Separate 4-way repeated measures analyses of variance for the 2 wave forms, wherein intervals, pairing, and trials were considered fixed factors and *S*s a random factor, supported these observations. These analyses yielded reliable pairing effects for both positive and negative potentials, $F\ (1, 29) = 28.05$ and 43.34, respectively, $p < .001$. Furthermore, as shown in Figure 1, conditioning appeared to be more pronounced in the second interval for both positive and negative potentials. This observation received only partial statistical support, however, since a reliable Pairing × Intervals interaction was obtained only for the negative response, $F\ (1, 29) = 9.84$, $p < .005$. Additionally, it should be noted that tests of simple main effects nesting pairing within intervals for the negative response resulted in reliable pairing effects for the first, $F\ (1, 58) = 11.05$, $p < .005$, as well as the second, $F\ (1, 58) = 51.04$, $p < .001$, interval. Finally, reliable Pairing × Trials interactions were obtained for both positive, $F\ (19, 551) = 3.58$, $p < .001$, and negative, $F\ (19, 551) = 1.89$, $p < .01$, potentials, which appeared to reflect the typical curvilinear nature of autonomic conditioning functions.

The overall frequency of responding was higher in the first interval than the second for both positive, $F\ (1, 29) = 24.95$, $p < .001$, and negative, $F\ (1, 29) = 39.43$, $p < .001$, potentials. It was also apparent that the negative potential evidenced a degree of response decrement across trials in the first, $F\ (19, 551) = 2.34$, $p < .001$, but not in the second interval, despite a reliable overall trials effect, $F\ (19, 551) = 3.59$, $p < .001$. In the positive response, only a trials effect was obtained, $F\ (19, 551) = 6.66$, $p < .001$.

Examination of intrasubject response frequencies in both ISI intervals revealed

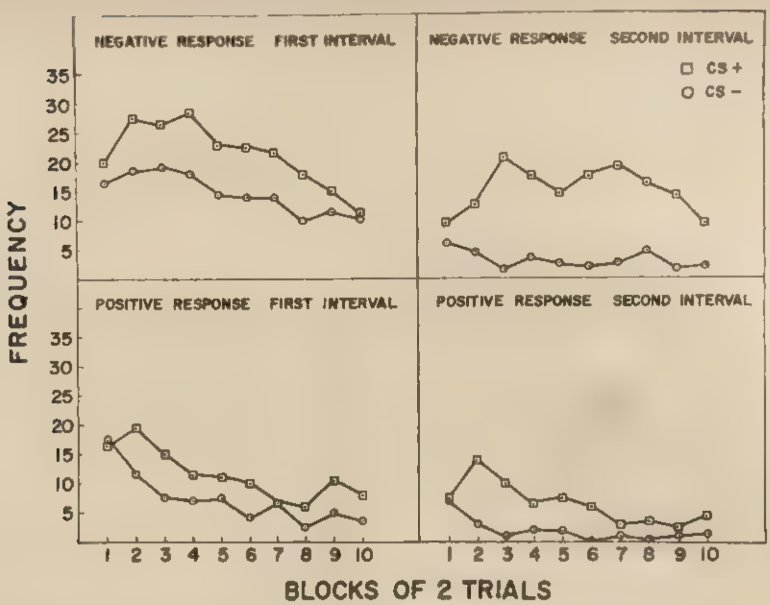

FIGURE 1. Frequency of positive and negative skin potential responses to positive and negative conditioned stimuli (CS+, CS−) in first and second portions of the interstimulus interval averaged over blocks of 2 trials.

additional details regarding the relative effect of conditioning on positive and negative potentials. These data indicated that in terms of overall frequency, *S*s tended to show a predominant response polarity. On the basis of the within-*S*s algebraic difference between frequency of responses to CS+ and CS−, [f(CS+) − f(CS−)], across the entire ISI, pairing effects were observed in 29 of the 30 *S*s, but these were greater across negative potentials in 20 *S*s and across positive potentials in 7 *S*s, while 2 *S*s failed to show a distinct pattern. Individual data also showed that in spite of overall conditioned response latencies, *S*s showing greatest conditioning across positive potentials exhibited such differences primarily during the first half of the ISI (5 of 7 *S*s), while those conditioning in the negative response showed greatest differentiation in the second interval (15 of 20 *S*s). A Fisher's exact probability test performed on these frequencies revealed that they were statistically significant, $p < .05$.

Since *S*s exhibited a strong tendency to condition primarily in terms of a single polarity, individual total responsiveness was examined to determine the degree to which each *S* responded in a consistent fashion to conditional and control stimuli. In 20 of the 30 *S*s, at least two thirds of the total responses made were of like polarity. Of the 20 *S*s showing such a degree of response predominance, 16 were negative responders while 4 responded positively.

Discussion

The results of the present study indicate that both components of the SPR are modified in classical conditioning, and further that conditioned effects occur in early as well as late portions of the ISI. Previous related research dealing with differential behavior of positive and negative potentials in classical conditioning has led to some inconsistent conclusions. Yamazaki et al. (1969) stated that the effects of conditioning are observed primarily in the negative potential, while Shmavonian et al. (1968) argued that the positive potential is most sensitive to pairing. The current research yielded no evidence that conditioning is manifested exclusively in either component. Although there appeared to be a greater pairing effect in terms of the negative component, this simply may have been a function of higher negative response frequency.

Dividing the ISI into 2 intervals and examining responses within these intervals separately permitted a determination of the temporal characteristics of the conditioned activity and provided some information with respect to the orienting response (OR). A comparison of short and long latency conditioned responses showed that conditioned effects for the negative potential are more pronounced in the latter portion of the ISI. This finding is in accord with the results of previous SRR studies employing long ISIs in that, in these studies as a whole, conditioned effects appeared more consistently later in the interval (Gale & Ax, 1968; Gale & Stern, 1967; Leonard & Winokur, 1963; McDonald & Johnson, 1965; Prokasy & Ebel, 1967; Stewart et al., 1961). It should be noted, however, that with the negative SPR and probably with the SRR, the attenuated pairing effects observed initially may result from OR components present primarily in the first portion of the interval. In the present study this was supported by the increased frequency of response to the CS− early in the ISI for the negative response. Elevated CS− response frequencies were also observed in the first interval for the positive potential; however, in this case, attenuated early pairing effects did not result.

Related to the observations concerning response frequency to the unpaired stimuli are the findings of investigators who have addressed themselves directly to the relationship between SPR polarity and orienting behavior. As with the conditioned response, some have associated orienting with the negative component (Raskin et al., 1969; Shmavonian et al., 1968), while others have assigned this property to the positive component (Loveless & Thetford, 1966; Yamazaki et al., 1969). In the present study, elevated frequencies were observed in the first interval for both potentials, suggesting that the OR may be manifested in either component.

Intrasubject response comparisons permitted a more precise interpretation of the effects of pairing on positive and negative skin potential components. Most *S*s exhibited a degree of differential responding in terms of both components. However, there was a tendency for *S*s to condition predominantly in terms of one component or the other. This propensity may reflect a stable characteristic of individual responsiveness, but probably can be better accounted for in terms of the interaction between individual and situational response determinants. The latter possibility is more likely in view of studies relating SPR components to stimuli of varying levels of threat, apprehension, or intensity (Burstein et al., 1965; Forbes & Bolles, 1936; Raskin et al., 1969). The previous work dealing with such relationships has been limited somewhat by its failure to consider individual differences in response to the stimulus. A model of SPR polarity incorporating individual response differences of this nature appears to be required in the interpretation of the results of the present study, since the same stimuli elicited positive and negative SPR components to varying degrees in different *S*s.

An additional finding apparent in the data of individual *S*s concerned the principal locus of differential responding for individuals exhibiting a predominant response polarity. Subjects showing a conditioned effect primarily in terms of the negative component displayed greater differential responding in the latter half of the ISI, while those showing more positive component conditioning did so earlier. This effect, which may in part account for the lack of differential pairing effects between the first and second intervals in the grouped data for the positive response, was probably due to the habituation rates of responses to the CS−, which appeared to be greater for the positive than for the negative potential in the first interval. While the reason for differential rates of habituation of positive and negative components is unclear, the effect has been noted by other investigators (Loveless & Thetford, 1966; Raskin et al., 1969; Yamazaki et al., 1969) who have, partially on the basis of such differences, attempted to relate response polarity to orienting behavior. Such an interpretation, of course, would not be consistent with a model of SPR activity emphasizing individual as well as situational determinants of responsiveness.

In summary, on the basis of the current research, several conclusions may be advanced tentatively regarding SPR conditioning which also relate to procedural considerations. First, since *S*s exhibit a predominant response polarity and have a tendency to display conditioned effects as well as orienting behavior primarily in terms of that polarity, a differential paradigm which provides intrasubject control for sensitization appears to be required. Second, because of the differential habituation rates of the positive and negative components, an adaptation session prior to conditioning may complicate matters and probably should be avoided. Finally, comparisons between the

present study and previous work suggest that frequency measures may provide a better index of conditioning since such measures presumably would be less distorted by rapid reversals in response polarity than would amplitude measures. Of course, further research is required to provide more definitive information concerning these issues.

LEVELS OF PROCESSING IN WORD RECOGNITION AND SUBSEQUENT FREE RECALL[1]

JOHN M. GARDINER[2]

Birkbeck College, University of London, London, England

The present experiment explored a situation in which *S*s were unexpectedly required to recall the target words from a perceptual decision-making task. The targets were defined with respect either to their phonemic or semantic attributes, and *S*s held these attributes in "working memory" for varying time intervals prior to target presentation. Semantically defined targets were better recalled subsequently than were phonemically defined targets, although the latter gave rise to longer decision latencies in the initial task. Also, subsequent target recall was not affected by the length of time the target-defining attributes had been held in working memory. These results were discussed within the context of Craik and Lockhart's "levels-of-processing" approach.

Craik and Lockhart (1972) described a framework for memory research in which the memory trace is viewed essentially as the by-product of perceptual analyses. Central to their argument is the notion that the stability of the memory trace is a positive function of the type and depth of processing involved in the encoding of perceptual events. Greater depth of processing is defined in terms of the degree of cognitive involvement in carrying out stimulus analyses. Memory is assumed to be tied to a continuum of levels of processing which range, for example, from sensory analyses to the activation of associative semantic attributes.

As Craik and Lockhart (1972) suggested, this formulation implies that research should be directed toward determining the memorial consequences of various types of perceptual operations. Craik (in press, Experiments IV and V), for example, reported 2 studies in which *S* was given an initial perceptual decision-making task followed by an unexpected memory test. The purpose of the initial decision-making task was to lead *S* to encode different words at different levels of analysis. For each of a series of words presented briefly in a tachistoscope, *S* was asked a question such as (*a*) Is there a word present? (*b*) Does the word rhyme with ____? (*c*) Is the word a member of the following category? or (*d*) Does the word fit into the following sentence? In general, Craik's results showed that "deeper" decisions about words gave rise both to longer decision latencies in the initial task, and to better memory performance subsequently.

These results are in good agreement with the levels-of-processing view. However, it could be argued that the differences obtained in memory performance were due to the corresponding differences in initial processing time, rather than due to increasing "depth" of analysis. Although words processed at "sentence level" were better remembered than words processed at "rhyme level," for example, *S* also took longer in making sentence level decisions.

The general aim of the present experiment was to obtain further evidence in support of the levels-of-processing approach. Again, the strategy was to examine the effects of depth of analysis in a perceptual decision-making task upon subsequent memory for "target" words. The present study was also designed to provide more information on the effects of initial processing time in such a situation. In this context, it is important to note that processing time refers, poten-

[1] This research was supported by a Science Research Council Postgraduate Award. The author is grateful to Fergus I. M. Craik and Peter Herriot for their helpful comments on an earlier draft of this article.

tially, both to the time *S* takes to process the target word as such and to the time *S* spends in processing those attributes that serve to define the target. The present paradigm permits the effects of these 2 processing times to be evaluated separately.

In essence, *S*s were presented with a series of word sets, each containing a unique target word. Prior to the presentation of each word set, *S* was given the "defining attributes" of the target word. For half of the *S*s, the target words were defined by their containing either 1 or 2 phonemes. For the remaining *S*s, the targets were defined as members of either a single category or a nested category. The target word POLAND, for example, might be defined as containing the phonemes /l/ or the phonemes /l/ and /n/, on the one hand, or as a country or a European country, on the other hand. Thus, one group of *S*s was required to identify targets at a "structural" level of analysis while the other group of *S*s had to identify targets at a deeper, semantic level. The *S*'s decision latencies in response to targets provided a measure of target-word processing time. In order to examine the effects of processing time for target-defining attributes, the number of nontarget words preceding the target in each set varied across trials. Thus, the length of time the target-defining attributes were held in "working memory" was indexed by the position of the target in any given word set. Following this perceptual decision-making task, *S*s were unexpectedly asked to write down all the target words they could remember.

The experiment had, therefore, the following 2 main objectives: (*a*) to compare recall performance following either phonemic or semantic processing of target words, and (*b*) to examine the relationship between initial processing times and subsequent recall.

Method

Subjects. The *S*s were 32 volunteers, mostly undergraduate students, who were either paid for their services or were fulfilling a course requirement. The *S*s were tested individually.

Design. The experiment was conducted [illegible]ing a mixed design. Level of processing (pho[illegible]r semantic) was the between-*S*s variable, ca[illegible]re for convenience "attribute type." Sixteen [illegible]re assigned at random to each between-*S*s [illegible]n. Within *S*s, the design comprised a factorial [illegible]om-bination involving 2 levels of "attribute nu[illegible]ber" and 4 levels of "attribute lag." Attribute nu[illegible]ber refers to target-word definition by either 1 [illegible]r 2 phonemes, on the one hand, or by a si[illegible] or nested category name, on the other hand. At[illegible]ute lag refers to the position of the target with[illegible]ach word set.

The *S*s were presented with 38 word [illegible]he target-recognition session. Prior to th[illegible]ta-tion of the first word in each set, th[illegible]for that set was defined either as a member o[illegible]gle or nested category for *S*s in the semant[illegible]di-tion, or by the word containing either 1 o[illegible]ven phonemes for *S*s in the phonemic conditio[illegible]The target word was always the final word in [illegible]set. On any given trial, it was preceded by 1 [illegible]n-target words. The critical positions of th[illegible]get for scoring purposes were 3, 4, 5, and 6. [illegible]ons 2 and 7 were included to reduce target pre[illegible]bil-ity by position; 6 of the 38 trials were of t[illegible]nd. The remaining 32 target words appeared [illegible]ally often at each of the 4 critical positions an[illegible] were defined equally often by either 1 or 2 att[illegible]butes in each between-*S*s condition. For presentation purposes, the total number of word sets was divided into 4 blocks which were counterbalanced with regard to presentation order and the level of attribute number. In effect, all *S*s received the same target words, and no target word was differentially favored with respect to order of presentation or experimental condition.

Approximately 2 min. after the final trial in the recognition sessions, *S*s were unexpectedly asked to write down, in any order, all of the target words they could remember.

Materials and procedure. Of the 32 critical target words, 27 were selected from the Battig and Montague (1969) category norms and the remaining 5 were chosen by *E*. Those drawn from the published norms had a mean frequency of occurrence of 16%. This relatively low value was chosen in order to minimize *S*'s chances of guessing the target word when given category names as the target-defining attributes. The frequency count for nontarget words ranged between 5–20/million (Thorndike & Lorge, 1944). All words, both targets and nontargets, were 2 syllables in length.

Two sets of presentation lists were constructed for each of the 4 levels of attribute lag. The difference between the 2 sets lay in the nontarget words in each; specifically, where target words were defined by 2 attributes, the preceding nontarget words always included 1–3 words that contained one or the other of the 2 defining phonemes and belonged to the single but not to the nested category. This procedure was designed to ensure that *S*s had to utilize both given attributes when targets were so defined.

The word lists were typed in uppercase letters for presentation via an *IBM* electric typewriter and a closed-circuit television system. A Birkbeck Laboratory Timer and Signal Source was used to both trigger the presentation of each word and also to start, simultaneously, a Venner millisecond stopclock. The Birkbeck Laboratory Timer and Signal Source was operated manually by *E*, contingent upon *S*'s having responded to the word currently presented. In practice, words within a set appeared at about a 2-sec. rate.

The *S*'s vocal response, amplified from a throat microphone, stopped the Venner timer. Each *S* was instructed to respond *yes* or *no* to each word as rapidly but as accurately as he could. In addition, *Ss* were instructed that after each *yes* response they were to report the target word aloud. The decision latency measure, however, was of course from the onset of the target word to *S*'s *yes* response.

The *Ss* were initially familiarized with the apparatus and procedure. They were also fully instructed as to the nature of the stimulus material. Prior to the experimental trials, each *S* received 6 practice trials in which the target word appeared once at each possible target position. Each trial began with *E* reading aloud the target-defining attributes for the word set. Consider, for example, the case where the target word was POLAND. If the target was defined by one attribute, *E* said either "the target contains the sound /l/," or "the target is a country," for *Ss* in the phonemic and semantic conditions, respectively. Where the target was defined by 2 attributes, *E* said either "the target contains the sounds /l/ and /n/," or "the target is a European country." Examples of target words and their corresponding 1- or 2-attribute definitions were: LEOPARD: /p/, or an animal; /p/ and /d/, or a wild animal; DUBLIN: /b/, or a city; /b/ and /n/, or a capital city; RICKETS: /k/, or a disease; /k/ and /t/, or a bone disease; TEMPLE: /m/, or a building; /m/ and /p/, or a religious building. Following target definition, each word in the set was presented, one word at a time. Examples of 2 presentation sets were: FATHOM, METEOR, ATTIC, POLAND, and FATHOM, JAPAN, ATTIC, POLAND. The latter example includes one distractor which contains 1 of the 2 target-defining phonemes and belongs to the main but not to the nested category: sets including one or more such distractors were presented when the target was defined by 2 attributes. Each trial terminated after *S* had correctly identified and named the target; the next trial began immediately.

The *Ss* were told that the point of the experiment was to investigate the effects of defining target words by 1 or 2 "values along a dimension" on the speed with which they could identify the target. No *S* reported subsequently that he had anticipated having to recall the target words.

Unknown to *Ss*, only decision latency in response to target words was recorded. Errors made by *S* in the target-recognition session were noted and "corrected" orally by *E* at the time of their occurrence.

RESULTS

For both the decision latency data and the recall data, Target Positions 3, 4, 5, and 6 (attribute lag) were collapsed into 2 levels of 3 plus 4 (short lag) and 5 plus 6 (long lag) in order to obtain more reliable estimates. The *E* errors and apparatus failures accounted for less than 2% of all responses in the target-recognition session; *S* errors accounted for 5% of responses in the semantic condition and 6% in the phonemic condition. Error data were excluded from all analyses. The results are shown in Figure 1.

Consideration is given first to the latency data. The basic datum was median reaction time for correct responses from the 8 trials each *S* received in the $2 \times 2 \times 2$ combination representing attribute type (phonemic or semantic), attribute number (1 or 2), and attribute lag (short or long). The mean median scores are shown in the left-hand panel of the figure; each point is based on approximately 120 observations. These data were subjected to an analysis of variance. The main effects due to attribute type, $F(1, 30) = 14.9$, attribute number, $F(1, 30) = 43.5$, and attribute lag, $F(1, 30) = 8.8$, were all significant at or beyond $p < .01$. The only significant interactions were the following: Attribute Type × Number, $F(1, 30) = 12.3$, $p < .01$, and Attribute Type × Lag, $F(1, 30) = 4.4$, $p < .05$.

No detailed interpretation of these results will be attempted. From the point of view of the subsequent argument, the most relevant feature in these data is that *Ss* took considerably longer to process target words at the phonemic level than they did when targets were defined semantically. This result might seem surprising in view of Shulman's (1970) finding that, in a probe-recognition task, homonyms were recognized more rapidly than synonyms. However, it should be noted that whereas homonyms can be identified on a "holistic" basis, target words in the present paradigm were identified on the basis of individual, constituent phonemes.

The right-hand panel in Figure 1 shows the percentage of target words which *Ss*

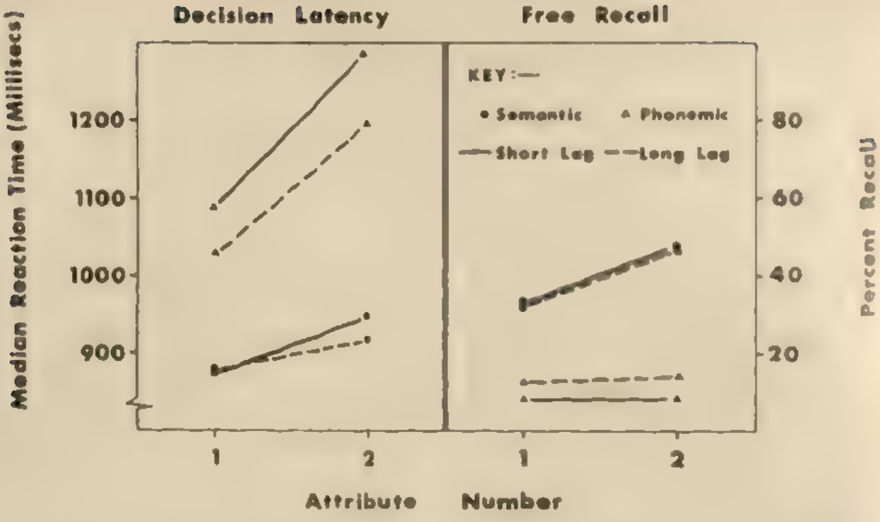

FIGURE 1. Decision latency and subsequent recall as a function to attribute type, number, and lag.

recalled in the final test, with the lag variable again collapsed into short and long lag. In order to obtain "workable" numbers for the purposes of analysis, the recall data supplied by each consecutively tested pair of *S*s were combined to form 8 macro-*S*s in each between-*S*s condition. An analysis of variance carried out on the macro-*S* recall scores confirmed that the main effect due to attribute type was highly significant, F (1, 14) = 73.2, $p < .001$. The main effect due to attribute number was also significant, F (1, 14) = 7.2, $p < .05$, but the main effect due to attribute lag was not ($F < 1$). The only significant interaction was Attribute Type × Number, F (1, 14) = 5.7, $p < .05$.

Not surprisingly, these results confirm that target words were recalled much better following semantic processing, as compared with phonemic processing, in the initial session. Recall of targets following phonemic processing is virtually at floor level. The results also indicate that the number of phonemes involved in processing the target had no effect upon recall performance. This finding contrasts with the comparable result in the semantic condition, where recall is better following target definition by a nested category than by a single category name.

Finally, it is apparent that the length of time the target-defining attributes were held in working memory (short or long attribute lag) did not affect subsequent recall of the target word. Neither the main effect due to attribute lag nor any interaction term involving lag approached significance.

Discussion

These results have several implications for the levels-of-processing approach discussed earlier. First, it is clear that processing target words at a semantic level led to good subsequent recall of the targets, whereas targets processed at a phonemic level were very poorly recalled. Similar differences in memory performance following semantic as opposed to structural processing have been reported by Craik (1973), Hyde and Jenkins (1969), and Schulman (1970). Such findings are in good agreement with the levels-of-processing view.

Although further analysis at a semantic level resulted in a corresponding improvement in recall (nested vs. single category names), additional analysis at a phonemic level did pot benefit recall. Thus, as Craik (1973) nointed out, the persistence of the memory trace should not be conceived to be simply a function of the number of analyses performed on the stimulus, but rather, a function of the degree of meaningfulness extracted from it.

The markedly poor recall of target words that had been processed at a phonemic level was associated with much longer decision latencies for these targets in the orienting task. Clearly, the pattern of results obtained in the recall test cannot be attributed to corresponding differences in the processing time for target words. It should be noted that following target-word recognition, *S*s were required to report the target word aloud. This procedure ensured that all target words were processed to at least a "nominal" level. The poor recall of phonemically defined targets must reflect the manner in which the words were processed, rather than the possibility that the target word as a whole was never perceived.

It was also found that the length of time the target-defining attributes were held in working memory did not affect subsequent recall of the target words. This finding relates well to Craik and Lockhart's (1972) suggestion that maintaining information at a "fixed" level of processing does not necessarily lead to any improvement in the memory trace. More generally, the present data demonstrate that duration at encoding is not nearly so crucial for registration in memory as are the levels of analysis involved. No evidence was found to support the notion that processing time, whether for target words or for target-defining attributes, was a critical factor for subsequent recall performance. The results imply that processing time may only be important insofar as it permits further or deeper levels of analysis to be carried out.

In summary, the present study explored a situation in which *S* was unexpectedly required to recall the target words he had identified in a perceptual decision-making task. The main findings were, first, recall of the target words was better following semantic as opposed to phonemic analysis of the target. Second, whereas further analyses at a semantic level led to a further improvement in recall, additional analyses at a phonemic level did not benefit recall. Third, neither processing time for target words, nor the length of time for which the target-defining attributes were held in working memory, appeared to be critical factors in determining subsequent recall performance. These results provide further support for the levels-of-processing view (Craik & Lockhart, 1972). It was concluded that the memorial consequences of the operations carried out in the perceptual decision-making task were attributable solely to the level of analysis these operations involved.

VISUAL AND AUDITORY CODING IN A MEMORY MATCHING TASK [1]

LARRY E. WOOD [2]

University of Wisconsin—Parkside

Two experiments were conducted to investigate modality-specific coding (auditory and visual) and recoding in a *same-different* reaction time task. On each trial 2 letters of the alphabet were presented sequentially in the same or in different modalities with an interstimulus interval of 150 msec or 3 sec. The coding dimension was inferred from differences in reaction time to contrasting sets of letter pairs, which were either aurally similar and visually dissimilar or vice versa. Similarity interacted with modality of the second stimulus, indicating that the stimuli were matched on the modality dimension of the second stimulus regardless of the modality of the first stimulus or the interstimulus interval. The results suggest that the first stimulus was recoded to the modality of the second for matching when the two were presented in different modalities and that visual coding was as effective as auditory coding in the task.

Although early research seemed to indicate that coding in short-term memory (STM) was auditory or acoustic in nature (e.g., Conrad, 1964; Wickelgren, 1965), later studies (e.g., Parks, Kroll, Salzberg, & Parkinson, 1972; Shulman, 1970; Tversky, 1969) have demonstrated considerable flexibility in coding processes and strategies. A task that has been particularly useful in studying coding processes is one in which *S*s are presented with 2 stimuli simultaneously or sequentially and are instructed to indicate as quickly as possible whether the stimuli are the same or different. Reaction time (RT) is the dependent measure of performance. For example, it has been found by several investigators (Beller, 1971; Posner, Boies, Eichelman, & Taylor, 1969; Posner & Mitchell, 1967) in a variety of conditions that *S*s are able to respond faster to pairs of letters that are physically the same (e.g., AA) than to pairs that only have the same name (e.g., Aa). The results seem to indicate that physical matches are made on the basis of visually coded information, but that name matches are made on the basis of aurally coded information. That is, before a name match is made, *S*s apparently recode the visual stimuli to their auditory equivalents, which leads to the longer RTs. More direct evidence that name matches are based on auditory information has been provided by Dainoff (1970) and Dainoff and Haber (1970), who found that name matches are affected by auditory similarity so that RTs were longer for similar pairs than for dissimilar pairs.

Tversky (1969) used a *same–different* RT task to demonstrate that the same information can be coded differently (either visually or verbally) depending on how *S* expects to use it. The stimuli consisted of line drawings of faces, each of which was associated with a name. Both types of stimuli varied on 3 binary dimensions, and the names and faces were paired so that similarity inversely covaried across the 2 types of stimuli. That is, faces differing by only one dimension were given names differing by 3 dimensions and vice versa, so that similar faces had dissimilar names and dissimilar faces had similar names. On each trial 2 stimuli were shown sequentially, with an interstimulus

[1] This study is based on a thesis submitted to the University of Iowa in 1971 in partial fulfillment of the requirements for the PhD degree. The author wishes to express his gratitude to James V. Hinrichs, who served as the chairman of the doctoral committee. The research reported herein was conducted while the author held Predoctoral Fellowship 1-F01-MH47899-01 awarded by the National Institute of Mental Health.

interval of 1 sec., and *S*s were asked to decide as quickly as possible whether or not the 2 stimuli had the same name. In each condition the first stimulus (S_1) was always either a name or a face, and the second stimulus (S_2) was randomly varied so that one type was shown on 79% of the trials and the other type was shown on the remaining 21% of the trials. Tversky reasoned that if *S*s could use either visual or verbal coding with equal ease and could readily recode stimuli from one mode to the other, then they should tend to code S_1 in the mode in which S_2 was expected (most frequently presented) regardless of the mode in which S_1 was presented. Such a strategy would result in longer RTs for those trials on which S_2 was presented in the unexpected modality because one of the stimuli would have to be recoded to the mode of the other before a match could be made. The predicted results were in fact obtained. Furthermore, analysis of the similarity effects showed that RT varied reliably as a function of the similarity of the S_2 mode, which indicated that the stimuli were matched on the S_2 mode independently of the S_1 mode.

Using a design similar to that employed by Tversky (1969), the present investigation was concerned with a comparison of visual and auditory coding and recoding in STM using letters of the alphabet as stimuli. The first experiment was performed to demonstrate that stimulus similarity manipulations could be used to infer the coding dimension, and the second experiment was an attempt to compare the relative effectiveness of visual and auditory coding and recoding as a function of the interval between stimuli to be matched by *S*. In order to determine the dimension on which stimuli were coded, the assumption was made that if RT in a matching task differed as a function of similarity along a specified dimension, then the stimuli were coded and matched on that dimension. Since the auditory and visual dimensions were the concern of the present investigation, letter pairs were constructed which were either high in auditory similarity and low in visual similarity (HALV) such as ZC, or low in auditory similarity and high in visual similarity (LAHV) such as OC. The expectation was that when stimuli were matched on the auditory dimension, HALV pairs would yield longer RTs than contrasting LAHV pairs. However, the opposite relationship would obtain between the 2 types of pairs when matches were made on the visual dimension.

Experiment I

Since differences in RT as a function of similarity were crucial in making inferences about stimulus coding, the first experiment was designed to demonstrate that the similarity manipulations described earlier (sets of contrasting HALV and LAHV stimulus pairs) would yield reliable differences. First, similarity effects are necessary in order to establish that coding and matching are occurring on the auditory or visual dimensions. Second, if the coding dimension in any given set of conditions is to be inferred from a particular pattern of similarity effects, it is necessary to show that a different pattern of similarity effects will obtain with the same sets of stimulus pairs and the same *S*s under different values of another independent variable. As discussed below, the independent variable chosen for this purpose was presentation modality.

Previous research with matching tasks has demonstrated that visual similarity affects RT with visual presentation of both stimuli of a pair (Clement & Carpenter, 1970) and auditory similarity affects RT with auditory presentation of both stimuli (McInish & Tikofsky, 1969). If presentation modality is a critical factor in coding for a matching task, then presentation of the same sets of contrasting HALV and LAHV letter pairs should reflect auditory coding with auditory presentation and visual coding with visual presentation. That is, with auditory presentation of both stimuli of each pair, HALV pairs should produce a longer mean RT than LAHV pairs, but with visual presentation, HALV pairs should produce a shorter mean RT

than LAHV pairs. Furthermore, the similarity effects should hold for the same *Ss* serving in both modality conditions.

Method

Subjects. The *Ss* were 10 female students from the introductory psychology courses at the University of Iowa. They were tested individually in 2 45-min. sessions on 2 successive days.

Design. Similarity (HALV and LAHV) and presentation modality (auditory and visual) were manipulated in a 2 × 2 factorial design with all *Ss* serving in all conditions.

Materials. As previously discussed, the predicted results of the present research were dependent upon significant differences in mean RT between contrasting pairs of letters conforming to a HALV or LAHV similarity classification. Therefore an attempt was made to construct letter pairs for which an opposite dichotomous classification on both similarity dimensions could be made. Visual similarity was defined simply as the amount of overlap in area between 2 uppercase letters, and auditory similarity was defined in terms of common phonemes shared by the letter names. Details of the similarity definitions can be found in Wood (1971). Four sets of letter pairs were constructed so that the 2 pairs in each set contained a common second letter with different first letters making up the appropriate similarity classifications. The four sets of HALV and LAHV pairs were ZC and OC, ZG and QG, VB and RB, and TP and RP. Both pairs of each set were terminated with a common letter in order to equate for perceptual differences among individual letters as a function of frequency, modality, etc., so that differences in RT between pairs could unambiguously be attributed to the similarity manipulations.

It should be noted that 6 of the 8 test pairs had a different first letter, which would enable *S* to predict the second letter of a pair rather accurately after being presented with the first letter. Hence, in order to create greater uncertainty regarding S_2 for the *different* pairs, 24 additional *different* pairs were constructed. Twelve of those pairs were constructed by combining each of the 6 different initial letters from the test pairs (Z, V, T, O, Q, R) with 2 of the 4 terminal letters (C, G, B, P) with which it had not been combined previously. The only restriction was that each of the 4 terminal letters was used for 3 of the pairs. The other 12 *different* pairs were constructed by pairing each of the 6 initial test-pair letters with the letters A and S as second letters. Finally, to create response uncertainty in the task, *same* pairs were constructed by combining each initial test-pair letter with itself 3 times, except for ZZ and RR which were used 4 times, making a total of 20 *same* pairs. Lists of 60 stimulus pairs were then constructed in which the 8 test pairs occurred twice each, the 24 additional *different* pairs occurred once each, and the 20 *same* pairs occurred once each.

Apparatus. The stimuli were presented visually on an Industrial Electronic Engineers Binaview display. For auditory presentation, the stimuli were tape-recorded and presented to *S* through earphones. The Binaview display was programmed by means of a punched-paper-tape reader which, in turn, was controlled by a BRS Electronics digital logic control system. The output of the tape recorder to be used for aural presentation was connected to the earphones through a set of relay contacts and to the BRS system for controlling the interstimulus interval (ISI) and intertrial interval for both auditory and visual presentation. A control signal from the paper-tape reader turned off the Binaview and closed the relay contacts to the earphones for aural presentation of a stimulus or turned on the Binaview and opened the relay contacts for visual presentation. Duration of the visual stimuli was 360 msec., the mean duration of the auditory stimuli as measured on an oscilloscope. The *Ss* responded to the stimuli by pushing one of 2 telegraph keys marked "same" or "different" and spaced 12 in. apart on a horizontal plane. The RTs (measured to the nearest millisecond) and the responses were recorded and punched onto paper tape.

Procedure. Each *S* received 5 blocks of trials, each consisting of a random order of the 60 stimulus pairs plus 6 practice pairs at the beginning of each block. The members of each stimulus pair were separated by 1 sec. measured from onset of the first stimulus (S_1) to onset of the second stimulus (S_2) and the pairs were separated by 3 sec. The order of the modality conditions was counterbalanced such that 5 of the *Ss* received visual presentation in the first session and 5 received auditory presentation first.

The *S* rested the index finger of each hand on one of the keys and was instructed to make a correct response as quickly as possible on each trial, indicating whether S_1 and S_2 were the same or different letters. A 2-min. rest period was given between each block of trials. The *same* response was always assigned to the dominant hand since there was no interest in directly comparing *same* and *different* responses.

Results

The first block of trials, the 6 practice trials in the remaining 4 blocks, and all trials on which errors were made were excluded from the analysis. Error rates ranged from 2%–5% across conditions. Since each test pair was presented twice in each block, there was a maximum of 8 correct trials per stimulus pair. A median RT was computed for each pair and then the 4 medians for each similarity condition (HALV or LAHV) were averaged, which resulted in a mean RT for

each S for each of the 4 similarity and modality conditions. These scores were then submitted to a 2-way analysis of variance.

The mean RT, *SE*, and percentage error for the 4 similarity and modality conditions are shown in Table 1. The hypothesis that similarity would have a different effect depending on the presentation modality was confirmed by a significant Similarity × Modality interaction, $F(1, 9) = 57.70, p < .001$. Comparisons of simple main effects of similarity within each modality condition indicated that with auditory presentation mean RT for HALV was significantly larger than that for LAHV ($p < .001$). However, with visual presentation the opposite relationship was obtained, so that the mean RT for HALV was significantly smaller than that for LAHV ($p < .01$).

Discussion

The finding that similarity did have a reliable effect in both presentation conditions is evidence that the stimuli were coded and matched on modality-specific dimensions. Of prime importance is the fact that the RTs for the same contrasting HALV and LAHV pairs reliably varied as a function of presentation modality for the same *S*s in both modality conditions. Since similarity was the only other variable which was systematically manipulated, it seems reasonable to conclude that the differences in RT found for auditory and visual presentation are attributable to the similarity manipulations. The results suggest that the procedure could be expected to produce reliable differences in RT among the stimuli from which modality-specific coding could be inferred in further investigation. Hence, the same stimuli were used in a second experiment to study some additional questions related to auditory and visual coding.

EXPERIMENT II

As discussed previously, Tversky (1969) found that the same information was coded visually or verbally in a matching task depending upon the mode in which S expected S_2 to be presented. Thus, it appeared that the information from S_1 was recoded from one mode to the other when necessary and that the mode of S_1 had little effect on the matching task. However, Tversky used an ISI of 1 sec., which is at the upper limit of the estimated duration of the auditory (Massaro, 1970) and visual (Sperling, 1960) sensory stores. It is possible that at much shorter intervals, the residual sensory information from S_1 might have an effect on the dimension in which the 2 stimuli would be coded for matching. Hence, if the 2 stimuli were presented in different modalities, S might recode S_2 to the dimension in which S_1 was presented in order to match the two. To test this hypothesis in the present study, conditions were used in which both stimuli of a pair were either presented in the same or in different modalities (auditory or visual) at an ISI of approximately 150 msec. For comparison, the *same* conditions were presented at a longer ISI of 3 sec., at which sensory information should have decayed and S_1 would have to be maintained for matching through some type of rehearsal. The similarity manipulations described in Experiment I were used to assess the coding dimensions.

If sensory information can be utilized in matching, then RT should be faster at the short ISI than at the long ISI, where the 2 stimuli are presented in the same modality. However, in the conditions where the stimuli are presented in different modalities (mixed), the need to recode one of the stimuli to the modality

of the other for matching would lead to larger RTs at the short ISI than at the long ISI if the recoding takes longer than 150 msec. Likewise, the need for recoding would produce slower matches at the short ISI for the mixed-modality conditions than for the same-modality conditions.

An additional consideration regarding the ISI manipulation is related to the proposition that S_1 could be maintained for 3 sec. only by rehearsal. Such a need may cause *S* to use auditory coding even when both stimuli are always presented visually. Dainoff (1970) and Posner et al. (1969) did find a tendency toward auditory coding as ISI increased from 0–2 sec., although the mixture of "physical" and "name" match conditions may have influenced *S*s toward auditory coding, as indicated by Posner et al. (Experiment III). In the present study, a direct test of the relative effectiveness of auditory and visual coding was provided in the conditions where both letters of a pair were presented in the same modality at 2 ISI values and *S*s were instructed simply to indicate whether or not the 2 letters of a pair were the same.

Method

Subjects. The *S*s were 64 female students from the introductory psychology courses at the University of Iowa. They were tested individually in 2 50-min. sessions on successive days.

Design. The design was a 2 × 2 × 2 × 2 factorial combination of 2 between-*S*s variables and 2 within-*S*s variables. The between-*S*s variables were modality of S_1 (auditory or visual) and modality of S_2 (auditory or visual). Sixteen *S*s served in each of the 4 S_1 and S_2 modality combinations. The within-*S*s variables were similarity (HALV and LAHV) and ISI (short and long). The actual ISI values were chosen so that the short ISI (approximately 150 msec.) would be well within the estimated duration of the short-term sensory stores but the long ISI (3 sec.) would be well beyond it.

Materials. The materials were the same as those used in Experiment I.

Apparatus. The apparatus was the same as that used in Experiment I.

Procedure. In each experimental session, *S* received 5 blocks of trials, each consisting of a different random order of the 60 stimulus pairs plus 6 practice pairs at the beginning of each block. The 5 blocks of trials were first recorded for the long ISI condition with an ISI of 3 sec. and an intertrial interval (ITI) of 4 sec. For the short condition, a copy of the original tape was cut spliced between the stimuli of each pair result in ISI values with a mean of 160 msec. an standard deviation of 20 msec., as measured an oscilloscope. The 5 blocks of trials wit each session were presented in a different o to each *S*, and the order of the 2 ISI conditi was counterbalanced so that half of the *S*s rece the short ISI condition first and half received long ISI condition first. To aid *S* in discrimina between the ISI and the ITI, a light on the sti ulus panel was turned on during the ITI. T *S*s were randomly assigned to one of the 4 and S_2 modality conditions according to thei pearance at the laboratory, with the restrict that the total number of *S*s in each group .. differed by more than one.

The *S* rested the index finger of each hand one of the keys and was instructed to attempt make a correct response as quickly as possibl each trial, thus indicating whether or not S_1 and were the same letter. The *S* was also inform of the S_1 and S_2 modalities and that the modali would remain constant throughout the exp mental session. A 2-min. rest period was given tween each block of trials. The *same* response w always assigned to the dominant hand since th was no interest in directly comparing *same* a *different* responses.

Results

As in Experiment I, the first block of trials, the 6 practice trials in the remaining 4 blocks, and all error trials were excluded from the analysis. Error rates ranged 1%–7% across conditions. For each *S* a median RT was computed for each test pair, and then the 4 medians corresponding to each similarity condition (HALV or LAHV) were used for computing means. These data were then submitted to a 4-way analysis of variance.

The hypothesis that the modality of S_1 would affect coding at the short ISI, but not at the long ISI, predicts an interaction of all 4 variables. However, only the modality of S_2 affected coding as reflected by a reliable Similarity × S_2 Modality interaction, F $(1, 56) = 143.31$, $p < .001$. In the conditions where S_2 was auditory, the overall mean RT for HALV was 55 msec. larger than that for LAHV ($p < .001$); however, for the conditions where S_2 was visual, mean RT for HALV was 20 msec. smaller than that for LAHV ($p < .01$). Thus in general, the effects of

similarity varied with the modality of S_2 regardless of the modality of S_1 or ISI. Mean RTs, *SE*s, and percentage error for the similarity conditions as a function of the other 3 independent variables are shown in Table 2.

One exception to the generalization that similarity effects varied as a function of S_2 modality occurred in the auditory S_1, visual S_2, long ISI condition, which led to a reliable Similarity × ISI × S_1 Modality interaction, F (1, 28) = 8.33, $p < .01$, in a separate analysis of the visual S_2 conditions. As shown in Table 2, the direction of the similarity difference was consistent with the other visual S_2 conditions but was only 7 msec., which failed to reach significance. One explanation for this result is that there were substantial similarity effects for each *S*, but the direction varied across *S*s. Individual *t* tests on the raw RTs for each *S*, however, failed to lend any support to this hypothesis. In general, the individual differences were rather small compared to the other visual S_2 conditions.

Earlier it was hypothesized that mixed-modality conditions might lead to slower matches than same-modality conditions at the short ISI, if the recoding of one stimulus to the modality of the other required more than 150 msec. To the contrary, however, a reliable S_1 Modality × S_2 Modality interaction, F (1, 56) = 6.03, $p < .025$, indicated that matches were faster in the mixed-modality conditions than where S_1 and S_2 were presented in the same modality. The *S*s responded 50 msec. faster in the visual–auditory conditions than in the auditory–auditory conditions and 58 msec. faster in the auditory–visual conditions than in the visual–visual conditions. Essentially the same pattern of results was also obtained from an analysis of *same* pairs.

Consistent with the hypothesis that sensory information can be used in matching, RTs at the short ISI were 40 msec. faster on the average than at the long ISI, F (1, 56) = 18.29, $p < .001$. The result was obtained for both the mixed- and same-modality conditions. Analysis of the *same* pairs again yielded an identical pattern of results.

Discussion

In using differences in RT to contrasting sets of letter pairs as a basis for making conclusions about coding, the assumption was made that the stimuli would be coded and matched on a common modality-specific dimension. The finding of reliable similarity effects in 7 of 8 conditions provides considerable support for that assumption. Since the similarity effects varied as a function of the S_2 modality in both the mixed- and same-modality conditions, it appears that the modality of S_1 had very little effect on the coding dimension, even at an ISI as short as 150 msec. Rather, *S*s still seemed to recode S_1 to the modality of S_2 when necessary, in

order to match the stimuli on the S_2 dimension. These results agree with those found by Tversky (1969), reviewed earlier, who used an ISI of 1 sec.

The agreement between Tversky's (1969) results and those of the present study is interesting in view of the procedural differences between the two other than the length of the ISI. First, Tversky randomly varied the mode of S_2 within an experimental session, whereas in the present study it remained constant. Second, Tversky used a considerably longer S_2 duration (4 sec.) than that of the present study (360 msec.). As reviewed earlier, Tversky's *S*s apparently matched the stimuli in the S_2 mode even when S_2 was presented in an unexpected (less frequent) mode, thus requiring a recoding of S_1 on those trials. It would seem that a recoding of the less frequent S_2 would be a more efficient strategy, but perhaps Tversky's use of the relatively long S_2 duration had an overriding influence toward matching in the S_2 mode. That is, a 4-sec. duration of S_2 would be more than enough time to recode S_1 as necessary and then sample the incoming sensory information from S_2 to complete the match. Thus, *S* would only be required to recode S_1 rather than to recode S_2 and retain S_1. Although a relatively short S_2 duration was used in the present study, matching in the S_2 dimension may have been due to keeping the S_2 modality constant during an experimental session. Thus the same results in the 2 studies may have occurred for different reasons.

One way in which a constant S_2 modality could have influenced the coding dimension in the present study is by providing *S* with a means to minimize the processing of S_2. This in turn would aid his following the instructions to respond as quickly as possible. Since the task was simply to decide if S_2 was the same stimulus as that previously presented, *S* could use information from S_1 to prime the perceptual mechanisms specific to a given modality for that same stimulus. In the same-modality conditions, the result of processing S_1 would merely have to be retained and used as a basis for testing the output from the same stage of processing S_2. The priming would be possible even when S_1 was presented in a different modality than S_2 but would require the additional processing necessary for recoding S_1. For example, an auditory S_1 would require a search of long-term memory for its visual equivalent, which could then be transferred to STM and used to prime the visual perceptual mechanisms for that particular letter. Facilitatory priming effects of advanced information have been found by Beller (1971) in a slightly different matching task for both same- and mixed-modality conditions.

Even though the modality of S_1 seems to have had very little effect on the matching dimension, there is some indication that residual sensory information from S_1 may have facilitated matching in the same-modality conditions. It is obvious th[illegible] in the long ISI conditions and the mixed-m[illegible]lity conditions sensory information from [illegible]ould not have played much of a role in [illegible] actual comparison process. In th[illegible] conditions the sensory information would [illegible]e decayed over the 3-sec. ISI and/or wou[illegible]ave only been a basis for recoding the stimu[illegible] to a different modality dimension. However, the finding that matches were faster at the short ISI than at the long ISI for the same-modality conditions is consistent with the notion that residual sensory information from S_1 could have been used to aid matching.

One result which ran counter to expectation was that matches in the mixed-modality conditions were faster than those in the same-modality conditions. The pattern of similarity effects indicates that S_1 was recoded to the modality of S_2 for matching in the mixed-modality conditions. Since the recoding would seem to require additional processing of S_1, the mixed-modality conditions were expected to be slower than the same-modality conditions rather than faster. Recent studies using memory match or memory search tasks (e.g., Burrows, 1972; Swanson, Johnson, & Briggs, 1972) have found RT in mixed-modality conditions to be either slower or no different from same-modality conditions. A tentative explanation for matches faster in the mixed- than in the same-modality conditions at the short ISI is that 150 msec. may not have been enough time for *S* to complete the necessary processing of S_1 when both stimuli were presented in the same modality, causing a delay in processing S_2. However, if it is assumed that the 2 modalities functioned as independent information channels that could be processed in parallel, there would be no delay in processing S_2 when it was presented in a different modality than was S_1. Evidence from studies using dichotic presentation of auditory stimuli (Norman, 1969; Peterson & Kroener, 1964)

provides some support for preliminary parallel processing of independent channels.

A final result of interest is related to the relative effectiveness of auditory and visual coding in STM. As stated earlier, the same-modality conditions provide a direct comparison of auditory and visual coding with all conditions equated except presentation modality. The finding that visual coding was used with visual presentation at both the long and short ISI seems to indicate that visual coding was as effective as auditory coding in the present study. These results are in agreement with those of other recent studies (Parks et al., 1972; Swanson et al., 1972) showing that *S*s can maintain visual information in STM beyond the duration of a sensory store, when there is a need to do so.

EVENT OBSERVATION IN PROBABILITY LEARNING REVISITED

LOWELL M. SCHIPPER,[1] JACK A. THORPE, DAVID P. JONES,
AND GARY W. HEIMAN

Bowling Green State University

A 1968 study by Reber and Millward investigated the possible differential effect of observing as compared with predicting sequences in subsequent probability learning. The present study extends the range of probabilities and the numbers of observing trials. Specifically, 0, 10, 35, and 60 observing trials and πs of .60, .70, .80, and .90 were combined orthogonally. Additionally, different random orders were used for each observing and each predicting sequence for all *S*s. A rather firm basis is made for pointing up the lack of difference between observing and predicting procedures in some important dimensions.

Reber and Millward (1968) addressed themselves to the same basic problem investigated here: What is the effect of observing sequences of events as compared with predicting sequences of events on subsequent predictions in a traditional probability learning (PL) situation? Reber and Millward provide a more than adequate theoretical rationale for the problem and little more need be said here to justify the research.

Unfortunately, the Reber and Millward (1968) study is something less than definitive in providing an answer to the question as posed, for a number of reasons. Only a single probability for the most frequently occurring event, A_1, was used, $\pi = .80$. Only a relatively gross evaluation of the effect of observation sequences as compared with prediction sequences could be made since either 0, 100, 500, or 2,000 observation trials (OTs) were provided for comparison. Only a very few (4) sequences were used in predicting or testing and another 4 in observing or training. Additionally, but of minor importance, the observation treatments omitted the signal light which was present during test trials.

The purpose of the present study is to enlarge upon the Reber and Millward (1968) study using 4 different levels of π for A_1, .60, .70, .80, and .90, and 4 different amounts of OT, 0, 10, 35, and 60 trials. Since we had speculated that fewer OTs might be required with higher values of π for *S* to reach near-terminal levels of performance than with lower values of π, this arrangement makes it possible to examine this differential effect as a joint function of observation trials and π.

Additionally, our point of view is that of considering PL—unfettered by complex payoff contingencies or by stimuli with affective or with painful complications (as examples)—as a relatively "pure" form of cognitive learning or information processing, different from other types of learning such as conditioning or motor skills learning. That is, there is little involved in the input (stimulus) or output (response) of this learning situation that is of any consequence compared with the internal processing of the information conveyed by the simple occurrence of events. This point of view, obviously, sees PL as a rather unique or atypical form of learning requiring little or no perceptual learning, little or no response training, and little or no associating of special responses with novel stimuli. As a consequence, simple observations of events seem to provide all that is necessary for learning—or, more precisely, for changing proportions of A_1 predictions as a function of trials—to take place.

Method

Apparatus. Each *S* sat at a table positioned in front of a gray display panel on which were mounted 2 blue event lights (A_1 and A_2) 15.23 cm. apart at approximately eye level and a single red signal light 7.61 cm. above and centered between A_1 and A_2.

[1] Requests for reprints should be sent to Lowell M. Schipper, Department of Psychology, Bowling Green State University, Bowling Green, Ohio 43403.

The response box on the table contained a center-off, double-throw lever switch, which was also centered between A_1 and A_2. Predictions of the occurrences of A_1 and A_2 were made by pushing the lever either to the left or right. The switch returned to center position when released by *S*.

Modified BRS-Foringer equipment controlled all timing, occurrences of A_1, A_2, and the signal light, and recording of all responses. Recording circuitry accepted as valid only those responses made during the particular 2-sec. interval when the signal light was on but before A_1 or A_2 appeared.

Design. Four levels of π for A_1 (.60, .70, .80, .90) were combined with 4 levels of OT (0, 10, 35, 60 trials) in a 4 × 4 factorial arrangement with 12 *S*s in each treatment. When appropriate, treatments will be identified as π/OT to indicate the particular combination of respective levels of each variable.

Three *E*s each ran 4 replicates of the experiment in random orders. Of the 4 *S*s for each *E* in each cell, 2 saw A_1 on the left and 2 on the right.

Procedure. For the 12 treatments with other than 0 OTs, each *S* simply saw either 10, 35, or 60 trials with either the left or right blue light coming on either 60%, 70%, 80%, or 90% of the time.[2] Of course, the complementary light appeared either 40%, 30%, 20%, or 10% of the time. During the OTs the signal light appeared for 1 sec. and was followed by an event light for 1.5 sec., which was followed by an intertrial interval of 1 sec. Following OTs each *S* received 100 test trials (TT) with the same π level that had been observed. Signal-light on time was increased to 2 sec. Other times remained the same. The 4 treatments receiving 0 OTs saw only 100 TTs at the appropriate π level.

All *S*s were run individually, one per session with *E* present. Essential parts of the instructions to *S*s were as follows.

With observation trials:

> Your job is to keep track of about how often each blue light comes on. That's all. Just keep track of how often each one comes on. It might seem as though the lights follow a *pattern* or *system*, but they *don't*. Just concern yourself with about how often each blue light comes on.

After observation trials were shown:

> Now this is important. For this series of trials, the *overall proportion* of lefts and rights will be exactly the same as the short series you just saw, although it will not be in the same order as the earlier series. Again, there will be no *pattern* or *system* although sometimes it might seem like there is. Your job is to be correct as often as possible. Try to be correct as many times as you can. Use what you learned about the proportions of lefts and rights in helping you predict as best you can.

Without observation trials (the principal portion of these instructions after the initial description of the procedure):

> Your job is to be correct as often as possible. Try to be correct as many times as you can. It might seem as though the lights follow a *pattern* or *system*, but they *don't*. Just concern yourself with getting as many correct predictions as you can.

Every one of the 144 sets of OTs was a different random arrangement, and every one of the 192 sets of TTs was also a different random arrangement.

Subjects. Female *S*s enrolled in introductory psychology courses at Bowling Green State University during the fall quarter of 1972 participated in this experiment as part of the psychology department's curricular requirements. Each *S* chose the experiment voluntarily and was permitted freedom to refuse to participate before and during her experimental session. None did.

Only a single sex was used in this sample of *S*s to prevent possible confounding of treatment with sex differences (Hanson & Schipper, 1971).

Results and Discussion

Figure 1 summarizes that portion of the data obtained during the 100 TTs for each S. The ordinate is the proportion of A_1 predictions; the successive abscissas are the first, second, and third thirds (33, 33, and 34 trials) of the 100 TTs; and the parameters for each subset of curves are the numbers of OTs. As expected, each subset fluctuates at or near the appropriate π level. The summary curves, one for each subset with its corresponding proportions of A_1 predictions attached, show no cross-overs. That is, the 3 points for .90 are all higher than the 3 points for .80, which are higher than .70, which are higher than .60. Regularity, vis-à-vis performance on TTs as a function of number of OTs, is *not* in evidence if one were to repeat the points of Figure 1 in subsets of 0 vs. 10 vs. 35 vs. 60 OTs with 4 curves in each family, one for each π value. Nor is there an orderly overall progression in response level as a function of increasing OTs from 0 through 60.

An analysis of variance of the data in Figure 1 using π and OTs as between-*S*s variables and blocks of trials (1–33, 34–66,

[2] Since 70% and 90% of 35 are 24.50 and 31.50, respectively, half of the *S*s in each of these treatments, half with each *E*, and half with left and right event lights received either 24 or 25 presentations of A_1 for .70 and either 31 or 32 presentations of A_1 for .90.

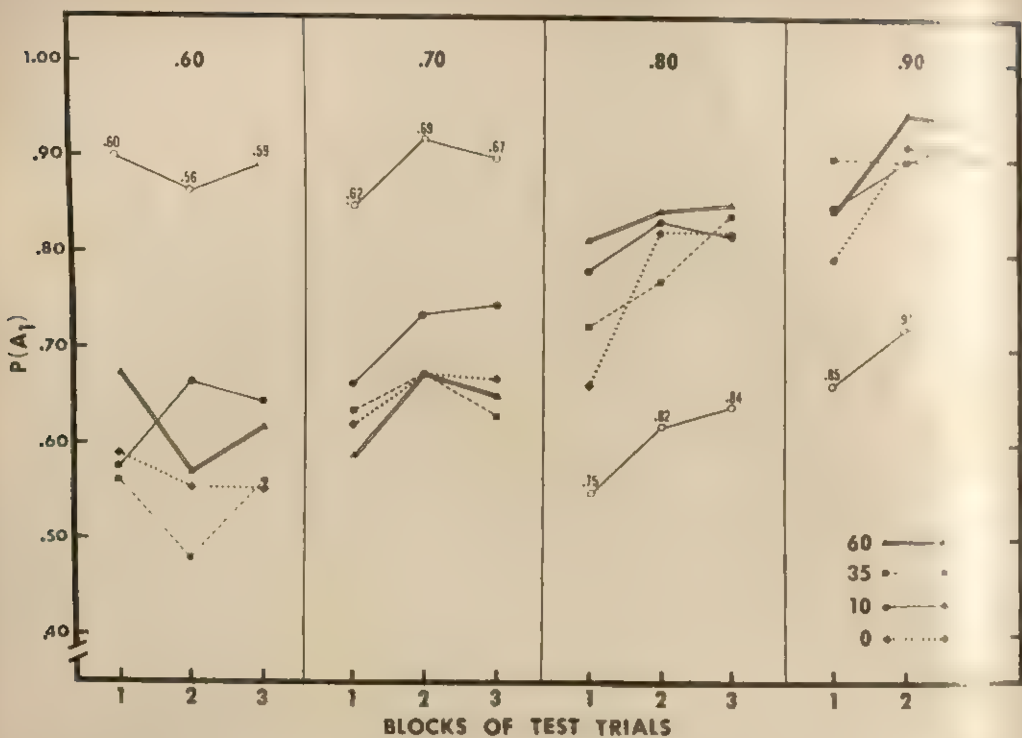

FIGURE 1. Proportion of A_1 predictions, $P(A_1)$, as functions of π (shown at the top of ea[illegible] [illegible]bset) and numbers of observation trials (shown in the lower right). (Curves with the values of th[illegible] [illegible]dinate attached reflect mean values for each subset. A_1 = most frequently occurring event.)

67–100) as a within-*S*s variable shows (*a*) differences in proportions of A_1 predictions as a function of π to be statistically reliable, $F(3, 176) = 92.39$, $p < .001$; (*b*) differences as a function of OTs to be reliable, $F(3, 176) = 3.02$, $p < .05$; and (*c*) blocks of trials, $F(2, 352) = 11.54$, $p < .001$, and the interaction of blocks and π, $F(6, 352) = 3.40$, $p < .005$, both reliable. The result of the first of these statistical tests is again expected and uninteresting. The third pair of tests gives statistical support to the interpretation of an increasing trend towards a higher response rate as a function of blocks with the caution that this trend is not the same for all π levels. The second statistical test, while showing that different numbers of OTs did bring about differencet in proportions of A_1 predictions, does nos expose the unexpected finding that the overall proportions are arranged 35 OTs (.713) < 0 OTs (.714) < 60 OTs (.750) < 10 OTs (.762) in increasing order, which shows no *systematic* (and little overall) variation attributable to numerosity of OTs.

Perhaps the most informative analysis of OTs vs. TTs is the use of staggered blocks of trials as originally suggested by Reber and Millward (1968). Two such analyses are presented here.

At each of the levels of π, Trials 67–100 for the 0 OT treatments, Trials 57–90 for the 10 OT treatments, Trials 32–65 for the 35 OT treatments, and Trials 7–40 for the 60 OT treatments were compared. This procedure essentially uses the data for the last block of 34 TTs in the 0 OT treatments as a referent and makes comparisons among (*a*) 66 TTs, (*b*) 10 OTs plus 56 TTs, (*c*) 35 OTs plus 31 TTs, and (*d*) 60 OTs plus 6 TTs (see top half of Figure 2). If observing and predicting have the same effect, then response curves for these different blocks for all levels of π should be

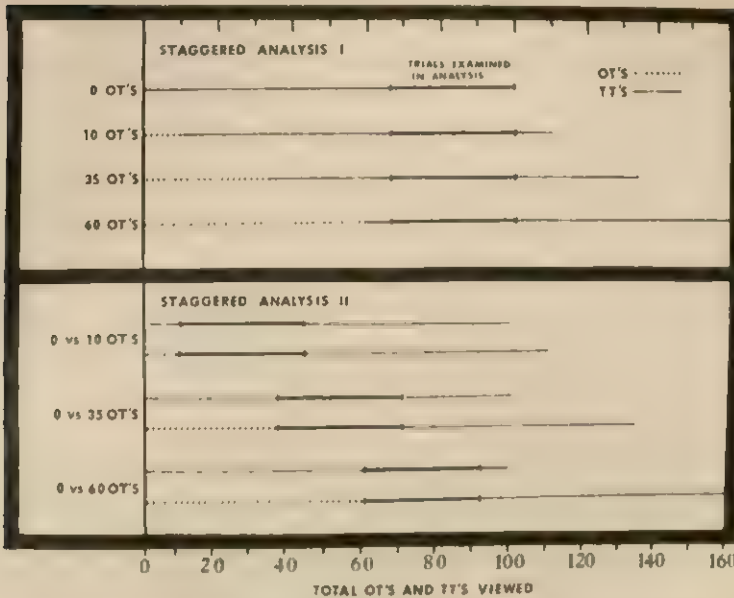

Figure 2. Test trials used for comparisons in first and second staggered analyses. (OT = observation trial; TT = test trial.)

horizontal. A summary of the results is shown in Figure 3.

... dinate in Figure 3 is again propor- ... predictions and the abscissa is ... r of observation trials. These ... re rather flat for $\pi = .80$ and ... ut rather nonflat for $\pi = .60$ and π ...

Treating these data as entries in a simple 4×4 factorial arrangement (with $n = 12$ in each cell), the differences in the 4 levels of the curves as a function of π yield F (3, 176) = 58.20, $p < .001$, and once again a predictable and expected finding. Differences between numbers of OTs yield F (3, 176) = 3.48, $p < .05$, which indicates

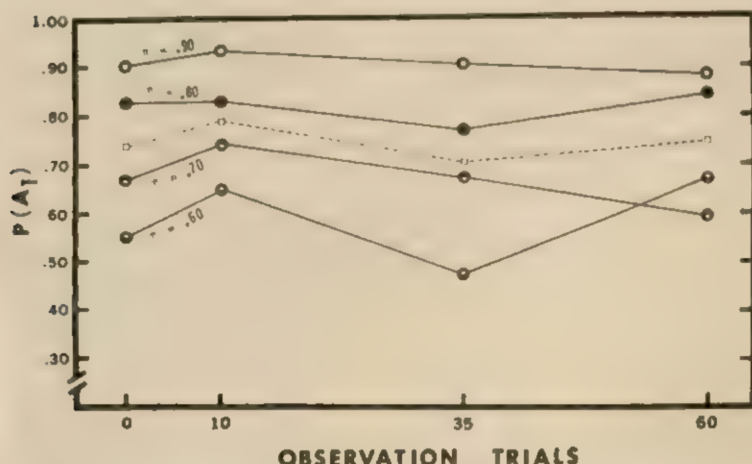

Figure 3. Staggered analysis showing comparisons among various combinations of observation and prediction trials. (The dashed curve is fitted to the 4 means at each level of observation trial. $P(A_1)$ = proportion of A_1 predictions; A_1 = most frequently occurring event.)

TABLE 1

PROPORTION OF A_1 RESPONSES AS A FUNCTION OF PRECEDING OBSERVATION AND TEST TRIALS AND AS A FUNCTION OF π

π	10		35		60	
	Observation	Test	Observation	Test	Observation	Test
.90	.853	.910	.900	.913	.850	.885
.80	.788	.738	.724	.825	.818	.838
.70	.662	.681	.630	.678	.584	.666
.60	.575	.562	.560	.542	.673	.571
M	.719	.723	.703	.739	.731	.740

Note. Entries for the Observation cells at the respective π values are mean proportion of A_1 (most frequently occurring event) responses for Test Trials 1–33. Entries for the corresponding Test cells are mean proportion of A_1 responses for Test Trials 11–43 when 10 observation trials were used for comparison; for Test Trials 36–68 when 35 observation trials were used for comparison; for Test Trials 61 93 when 60 observation trials were used for comparison. For example, the entry in the .90/10 Observation cell is the mean for *S*s who had received 10 observation trials prior to the measured 33 test trials. The entry in the .90/10 Test cell is the mean for *S*s who had received 10 test trials prior to the 33 measured test trials. Each entry for the Observation cells is based on 12 different *S*s. Each entry for Test cells .90/10, .90/35, and .90/60 is based on only those 12 *S*s who received the .90/0 treatment. Similarly, the .80/10, .80/35, and .80/60 Test cells are based on the 12 *S*s who made up the .80/0 treatment, and so forth.

an overall deviation from flatness when data are averaged over π levels and a single point is plotted for each of the OTs. The interaction of π and OTs, F (9, 176) = 2.05, $p < .05$, is also reliable and represents, of course, the lack of parallelness of the 4 curves shown in Figure 3.

A second staggered analysis, somewhat more complicated than the first, is illustrated in the bottom half of Figure 2. Essentially what this analysis does is provide a look at TT performance shifted farther and farther "down the line" in the TT sequence as a function of the number of OTs substituted for TTs. Table 1 summarizes this analysis, and a complete description of the nature of each entry is given with the table.

To be noted in Table 1 is the similarity between the means for 10 OT and 10 TT treatments, .719 and .723; for 35 OT and 35 TT, .703 and .739; and for 60 OT and 60 TT, .731 and .740, with 95% confidence intervals for the differences between each of these 3 pairs of means equal to ±.054, ±.048, and ±.049, respectively. Differences appear to be truly minute and suggest only a slight (if any) difference in a positive direction toward the programmed mean π of .75.

Statistical tests of differences between pairs of columns in Table 1, 10 OT vs. 10 TT, 35 OT vs. 35 TT, and 60 OT vs. 60 TT, with the 4 values of π as a second variable, uniformly show statistically reliable differences for π (again, as would be expected) and give F ratios of less than unity for 10 OT vs. 10 TT and 60 OT vs. 60 TT, and F (1, 88) = 2.18, $.10 < p < .25$, for 35 OT vs. 35 TT. All 3 of the interactions of π and type of trials give F ratios with confidence levels exceeding .05, and only one of these, that for 60 trials, is close to .05.

Still another analysis, that of trends, can be carried out to answer the question of whether or not the collective set of curves in Figure 2 is flat, linear with slope other than zero, quadratic, or cubic in form. According to a hypothesis of no difference between OTs and TTs, flatness is expected.

Using a procedure outlined in Saito (1965) for unequally spaced values on the abscissa, only the cubic form of the polynomial provides an F ratio which "accounts for" a statistically significant portion of the variance attributable to numbers of OTs, F (1, 176) = 8.71, $p < .005$. This cubic expression reflects the 2 inflections which are apparent when plotting only the 4 means as shown by the dashed curve in Figure 3.

A final look at what occurred during TTs is given in Table 2. This table shows the distributions of *S*s along all dimensions of the study during the successive thirds as well as during the complete set of 100 TTs. Deserving of special attention are the distributions of variances for 0, 10, 35, and 60 OT treatments at successive stages of the experiment. These OTs represent the principal variable in the experiment, and lack of homogeneity here could invalidate tests of significance among their means.

Cochran's C statistic with $k = 4$, 47 *df*, and $\alpha = .05$ for each appropriate set of 4 variance estimates shows that there is no basis for rejecting a hypothesis of homogeneous variability at any of the 3 stages of TTs, nor among the overall distributions.

Overall, we feel there is little difference between types of trials in terms of subsequent performance in the traditional PL

Note. The entries in the respective 60, 70, 80, and 90 columns show the distributions of those 12 *S*s giving A1 (most frequently occurring event) responses who had received 0, 10, 35, and 60 observation trials. The 4 All columns show the distributions of all 48 *S*s with 0, 10, 35, and 60 observation trials.

[a] Variances of the All distributions in the 0, 10, 35, and 60 observation trials conditions are σ^2 = 253.78, 338.89, 332.64, and 228.48, respectively.

[b] Variances of the All distributions in the 0, 10, 35, and 60 observation trials conditions are σ^2 = 300.20, 199.83, 466.62, and 335.38, respectively.

[c] Variances of the All distributions in the 0, 10, 35, and 60 observation trials conditions are σ^2 = 320.79, 208.16, 414.40, and 312.33, respectively.

[d] Variances of the All distributions in the 0, 10, 35, and 60 observation trials conditions are σ^2 = 195.14, 166.49, 295.66, and 241.49, respectively.

situation. We agree with Estes' (1972) interpretation of the Reber and Millward (1968) experiment saying approximately the same thing. Some differences may be a function of the particular π levels used, with these differences probably observable near $\pi = .50$ but not near extreme values.

RETRIEVAL OF SUPERORDINATES AND SUBORDINATES [1]

ELIZABETH F. LOFTUS [2]
University of Washington

MARTIN BOLTON
New School for Social Research

Semantic memory retrieval was investigated in 2 experiments. In the first experiment, *S*s were shown a category name and asked to respond with a word belonging to the category (for one block of trials) or a class to which the category name belonged (for another block of trials). Subjects produced a category member faster than they produced a superordinate. For example, they produced an instance of the category CAR faster than they produced a superordinate such as *vehicle*. The time taken to retrieve a superordinate was strongly related to the category's hierarchical position, while the time taken to retrieve an instance was not so related. In the second experiment, *S*s produced free associates to categories differing in hierarchical level. More subordinates were given for all but the lowest level categories. The data argue against the notion that the superset is the most accessible property of a category or concept.

The present article deals with relations of class inclusion, relations which have been of interest at least since Aristotle's time. Knowledge of these inclusion relations is knowledge that we have learned some time ago and know very well; it forms a part of our semantic memory. Whenever we make a subordinate or superordinate response, as when we assert that (*a*) an example of a dog is a collie, or (*b*) the class to which collies belong is "dogs," we manifest our knowledge of inclusion relations.

Class inclusion relations have become central in many current theories of memory. In the network model of Rumelhart, Lindsay, and Norman (1972), for example, a statement such as "A car is a vehicle" is represented as 2 nodes, one corresponding to "car" and the other to "vehicle," and a relation between them, the "isa" relation. One question that arises is what directional effects in information retrieval exist as a consequence of these inclusion relations? For example, given the stimulus word CAR, is it easier to retrieve a superordinate response, such as *vehicle*, *object*, or *thing*, or it is easier to retrieve an instance, such as *Ford*, *Buick*, or *Ferrari?*

Miller (1969) claims that "a superordinate response will be much stronger (more frequent and probably faster) than a subordinate response [p. 231]." He points to results from word association tests to support his claim. For example, the results of a reclassification of the data of Kent and Rosanoff (1910) indicated that 7.6% of all the responses given were superordinate and only 1.6% were subordinate (Woodrow & Lowell, 1916). From this evidence, Miller concluded that the subordinate–superordinate direction of association is stronger than the superordinate–subordinate direction. Collins and Quillian (1972) seem to be in agreement with Miller, as they say "in many cases the superset is the most accessible property of a concept. . . . In contrast, the instances of a concept are not easily accessible properties in general [p. 320]."

Rather than trust "indirect" data from word association tests to settle the matter of directionality, an experiment was performed in which *S*s were shown a word on each trial and were asked to name an instance (for one block of trials) or a superordinate (for another block of trials). The *S*s were timed while they produced their responses.

Experiment I

Method

Subjects. The *S*s were 22 students at the New School for Social Research. Each *S* took part in one experimental session that lasted 30 min.

[a] Categories for which production of superordinates was faster than production of instances.

Materials. Twenty pairs of nested category names were constructed. For each pair of categories, the superordinate category (Level 1) included everything that belonged in the subordinate category (Level 2). The nested categories used are presented in Table 1. The category names were printed on 5 × 8 in. index cards, with one category per card. Each *S* received 2 random permutations of the 40 cards. Half of the *S*s named superordinates on the first 40 trials, and subordinates on the last 40 trials. The reverse arrangement held for the remaining *S*s.

Procedure. Each *S* was told that we were conducting a study on how memory works, that he would see items consisting of single words, and that he was to respond with a word that was a superordinate (subordinate) of the stimulus word. He was given examples and told to respond as quickly as possible, but to avoid errors.

The *S* sat in front of a screen in which there was a window covered by half-silvered glass. The index card containing the stimulus was placed in a dark enclosure behind the mirror and was presented by illuminating the enclosure. A microphone was placed in front of *S* and he responded by speaking into it.

A trial consisted of the following events. As a card with the item printed in large type was placed in the darkened enclosure behind the half-silvered mirror, *E* said "Ready," and pressed a button that illuminated the stimulus. The *S*'s verbal response activated a voice key that stopped the clock and terminated the trial. If *S* did not respond within 10 sec., the trial was terminated. A warm-up period of 10 trials, using stimuli different from those used for the experimental trials, preceded each block of experimental trials.

Results

Only correct responses (96%) to the 20 pairs of nested categories are included in the following analyses. For each of the nested pairs, one category is more inclusive (higher in the semantic hierarchy) than the other. For example, VEHICLE includes more instances than CAR; in some sense, CAR is lower in the hierarchy than VEHICLE. We designated the higher category "Level 1" and the lower category "Level 2," and we computed a Level 1 and Level 2 median reaction time (RT) for each *S* for each of the 2 types of responses (subordinate and superordinate).

A 2 × 2 repeated measures analysis of variance indicated that the speed of producing a subordinate was significantly faster than the speed of producing a superordinate, F (1, 21) = 46.46, $p < .01$. All 22 *S*s showed this effect. Furthermore,

there was a significant effect of hierarchical position of a category on the time taken to respond, F (1, 21) = 9.86, $p < .01$. The interaction was also significant, F (1, 21) = 12.94, $p < .01$, indicating that the mean time taken to produce a superordinate was influenced by category level, while the time to produce a subordinate was not so influenced.

Median RTs were computed for subordinate and superordinate responses to each of the 40 categories and are presented in Table 1. For 32 stimulus words, *S*s produced a subordinate faster than he produced a superordinate; for 6 stimuli, the reverse result occurred.

Discussion

The finding that subordinates are produced more quickly than superordinates is inconsistent with Miller's (1969) and Collins and Quillian's (1972) intuitions that a superordinate is more accessible than a subordinate. On the other hand, Woodworth and Wells (1911) found that *S* produces superordinates faster than he produces subordinates, which is, of course, opposite to our own result. To reconcile their data with the present results, we must examine the Woodworth and Wells procedure more closely. In their experiment, 13 *S*s named superordinates of 20 stimulus words (for example, *S*s produced a superordinate for OAK and for CABBAGE, etc.) and they named subordinates of 20 *different* words (for example, TREE and VEGETABLE). A comparison of the average time taken for the 2 types of responses indicated a shorter RT for naming superordinates.

Although the present procedure is sounder than that of Woodworth and Wells (1911) in that we use the same stimulus words for the production of both superordinates and subordinates, the discrepancy between the 2 studies must be explained. A closer examination of the Woodworth and Wells stimulus words indicated that at least 12 of the words in the "name a superordinate" test were themselves instances of the words in the "name a subordinate" test. For example, *S*s were required to name a superordinate of OAK, CABBAGE, and PENNY, but to name subordinates of TREE, VEGETABLE, and COIN. Not only were the words for which *S*s produced superordinates lower in any assumed hierarchical structure than the words for the "subordinate test," but these words were lower than the words we used in Experiment I. Thus, the words for which Woodworth and Wells' *S*s produced superordinates would constitute, in our terminology, a "Level 3." These observations suggested the possibility that the discrepancy between the Woodworth and Wells study and the present study was due to item differences (specifically in hierarchical level) between the 2 studies. To test this possibility, Experiment II was designed.

Experiment II

Method

Subjects. The *S*s were 22 college students, none of whom had participated in Experiment I.

Materials. The 20 pairs of nested categories shown in Table 1 were used. In addition, a group of Level 3 categories was created by selecting one subordinate for each of the Level 2 categories. So, for example, for the pair FOOD–VEGETABLE, we selected the stimulus LETTUCE. Each *S* was presented a random permutation of the 60 unique categories.

Procedure. The *S*s were told that we were conducting an experiment on free association. They were told that they would see a series of 60 stimulus words, and after seeing each word, they were to write down the first word that it made them think of.

Results

A simple count was made of all response words which were superordinate and those which were subordinate. In case of any doubt, the simple question "Does one of these words belong to the class of things named by the other word?" would usually solve the problem. This technique has been used successfully by Peters (1952). In Figure 1, the mean numbers of these 2 types of responses are presented separately for the 3 levels of stimulus words. A 2 (response type) $\times$ 3 (hierarchical level) $\times$ 22 (*S*s) analysis of variance indicated that more subordinates than superordinates were given, F (1, 21) = 43.90, $p < .01$. Also significant were hierarchical level F (2, 42) = 32.94, $p < .01$, and the Level $\times$ Response Type interaction, F (2, 42) = 170.37, $p < .01$. A 2 (response type) $\times$ 3 (levels) $\times$ 20 (category triplet) analysis of variance gave identical results, namely, significant response type, level, and interaction effects.

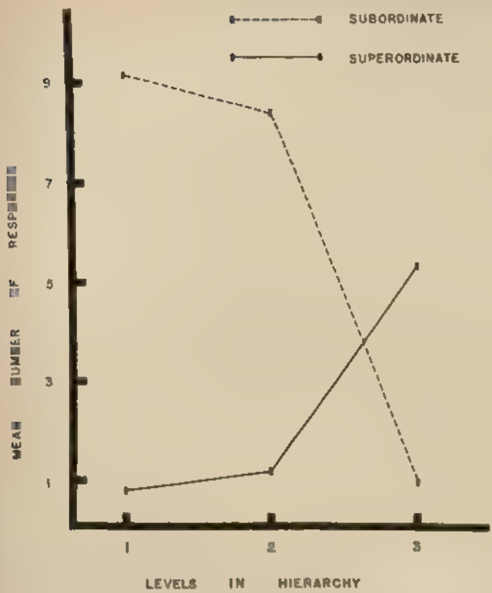

FIGURE 1. Mean number of subordinate and superordinate responses given in Experiment II.

General Discussion

Whether or not the superordinate or subordinate is the stronger depends on the level of the stimulus word in the semantic hierarchy. At Levels 1 and 2, more subordinates are given as free associates (Experiment II) and subordinate responses are given faster (Experiment I). At the lowest level, Level 3, more superordinates are given as free associations, and presumably superordinate responses would be given faster. At this level, *S*s appear to have few (if any) subordinate responses available. The reader can verify this fact by attempting to produce some instances of CABBAGE or PENNY. Subordinate responses are unlikely as free associates, but, if forced, *S* might reply with *red cabbage* or *copper penny*. Responses are highly idiosyncratic and correct single-word responses rarely occur.

The finding in Experiment I that the mean time taken to produce a subordinate when given a Level 1 category was not different from the time taken to produce a subordinate to a Level 2 category replicates an earlier study of Loftus, Freedman, and Loftus (1970), which showed that the RT taken to retrieve a member of a given category was not significantly different from the RT taken to retrieve a member of a superset of that category. Hierarchical position of a category does, however, affect the speed of producing superordinates. The RT taken to produce a superordinate of a Level 2 category such as CAR was faster than the RT taken to produce a superordinate of a Level 1 category such as VEHICLE. Thus, the more specific a word is, the faster *S*s can produce a superordinate for that word. In fact, an examination of the 6 categories listed in Table 1 for which production of superordinates was faster than production of instances reveals that 5 of the categories are the lower member of their respective nested pair. Thus, not only do some Level 2 (or specific) categories have a readily accessible superordinate, but they do not have as accessible an instance. There are so few of these cases (and in all 6, there is less than .8-sec. difference in the RT to produce a subordinate vs. a superordinate), that we find it difficult to agree with any overall statement that "the instances of a concept are not easily accessible [Collins & Quillian, 1972, p. 320]." In fact, the results of both experiments point out the need for recognizing that statements such as "the subordinate–superordinate direction of association is stronger" (cf. Miller, 1969) are, at best, only sometimes true

PUNISHMENT OF APPETITIVELY REINFORCED INSTRUMENTAL BEHAVIOR:

FACTORS AFFECTING RESPONSE PERSISTENCE

DENNIS G. DYCK[1]
Pepperdine University

ROGER L. MELLGREN
University of Oklahoma

JACK R. NATION
University of Oklahoma

In the first of 2 runway investigations, 2 groups of rats received equal amounts of punishment and nonreinforcement during acquisition training. Group PR received transitions from punishment to reinforcement and Group NR received transitions from nonreinforcement to reinforcement. A control group received unpunished continuous-reinforcement training. Following training, half of the *Ss* in each group received punished extinction, and the other half received unpunished extinction. The results indicated that Group PR was superior to Group NR in punished extinction, and the reverse was true in unpunished extinction. The control group exhibited the poorest performance regardless of the response-decrement procedure employed. In the second experiment, Groups NR and PR received unpunished, punished, and unpunished extinction following acquisition. Generally, the results were consistent with those obtained in the first experiment. These results were interpreted in terms of Capaldi's 1967 sequential theory of instrumental learning.

It is a well-established finding that partial punishment increases response persistence to continuous punishment over and above that produced by partial reinforcement (e.g., Banks, 1966a, 1966b; Brown & Wagner, 1964). Response persistence is increased more readily when punishment (P) is administered on nonreinforced (N) trials rather than reinforced (R) trials (Fallon, 1968, 1969), although persistence effects (relative to unpunished controls) have been observed in situations where punishment has been presented simultaneously with reinforcement (i.e., Banks, 1966b; Brown & Wagner, 1964).

Persistence effects due to punishment have traditionally been interpreted via an extension (Wagner, 1966) of Amsel's (1962, 1967) analysis of frustrative nonreward. However, several recent attempts have been made to extend Capaldi's (1967) sequential theory to account for the effects of punishment upon instrumental performance (Campbell, Crumbaugh, Marshall, & Sparling, 1972; Campbell, Crumbaugh, Massey, & Reed, 1972; Campbell, Wroten, & Cleveland, in press; Capaldi & Levy, 1972).

According to a sequential analysis, the mechanism of increased persistence depends upon the sequence of different goal-box events and not on the "number" of such events per se (Capaldi & Kassover, 1970). In a partial-reinforcement situation, resistance to extinction is increased when the memory of nonreinforcement (S^N) is conditioned to the instrumental response (R_I). Sequence is an important variable due to the fact that S^N is conditioned to R_I only on reinforced trials that have been preceded by nonreinforced trials.

Assuming that punishment results in a memory (S^P) like S^N, it may be conditioned to R_I on reinforced trials that follow punished trials (P–R transitions). It follows that differential trial sequencing should produce differential response persistence. This hypothesis has been supported in 2 separate investigations (Campbell et al., in press; Capaldi & Levy, 1972). In both studies, it was found that response persistence to punished extinction was increased

[1] Requests for reprints should be sent to Dennis G. Dyck, who is now at the Department of Psychology, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada.

by partial-punishment schedules containing P–R transitions relative to schedules containing only R–P transitions. Thus, preliminary evidence suggests that P–R transitions increase response persistence in a manner similar to N–R transitions. In addition, Capaldi and Levy found that groups which received punishment prior to large reward performed better over a series of punished trials than a group which received punishment prior to small reward. This finding indicates that the sequence of punishment–reinforcement events, not the ordinal position of punishment in the daily series of trials, determined performance.

The present experiments were designed to further explore the effects of sequential manipulations using both punishment and nonreinforcement. Accordingly, in the first of 2 experiments, 2 groups of *S*s experienced partial punishment–partial reinforcement training, so that one group (Group PR) received P–R transitions and the other group (Group NR) received N–R transitions. A third group received continuous reinforcement (Group RR). It should be noted that both experimental groups received the same number of nonreinforcement–reinforcement–punishment events; only the trial sequence of these events was varied. Following training, the 3 groups were split in half so that half of the *S*s in each group received punished extinction and the other half received unpunished extinction. The unpunished-extinction and punished-extinction procedures will be referred to as *response-decrement procedures.* It was hypothesized that differential group performance would be a function of the interaction between the type of training sequence and the kind of response-decrement procedure used in testing. Specifically, it was assumed that the stimulus complex in punished extinction would be dominated by punishment stimuli (S^P) and therefore *S*s trained with theoretical S^P–R_I associations (Group PR) should be superior to *S*s trained with theoretical S^N–R_I associations (Group NR). Conversely, the opposite prediction was made for *S*s receiving unpunished extinction. That is, Group NR was expected to show greater persistence relative to Group PR in unpu[illegible] extinction (i.e., since unpunished [illegible]tion would occasion nonreinforceme[illegible]ory stimuli). Of course, Group R[illegible] expected to show the least pers[illegible] regardless of the response-decr[illegible] procedure employed.

Experiment 1

Method

Subjects. The *S*s were 60 experime[illegible]y naive male albino rats of the Sprague-Daw[illegible] strain, purchased from the Holtzman Co. [illegible] were housed individually and were approx[illegible]ely 70 days old at the start of the experiment[illegible] The *S*s were randomly assigned to 1 of 3 ex[illegible]mental groups ($n = 20$ group).

Apparatus. The apparatus consisted [illegible] single straight-alley runway manufactured by [illegible]Hunter. The alley, which was 150 × 15 × 9 cm., [illegible]as constructed of clear Plexiglas with a grid flo[illegible] It was divided into a 30-cm. start section, a [illegible]m. run section, and a 30-cm. goal section, all sec[illegible]s being separated by guillotine doors. A teaspoon [illegible]ounted in the middle of the far end of the goal [illegible] served as a food cup. The *S*'s progress in the [illegible]ey was measured by 3 .01-sec. Standard Electric [illegible] Corp. timers. The first timer, which measured [illegible] time, was started by a microswitch at the start-box door and stopped by a photocell located 11 cm. into the alley. The second timer, which measured run time, was started by the first photocell and stopped by a second photocell located 11 cm. in front of the goal box. The third timer, which measured goal time, was started by the second photocell and stopped by a third photocell located 9 cm. inside the goal box. Start, run, and goal speeds were obtained by converting the start, run, and goal times to reciprocals. Total speeds were obtained by summing the start, run, and goal times and reciprocating this measure. Punishment consisted of a .3-ma. scrambled shock which was gradually increased to .5 ma. for .5 sec., administered in the goal section of the alley by a Model 700 Grason-Stadler shock generator. The shock was administered manually by pushing a button on the apparatus control panel.

Procedure. For 3 days after arrival in the laboratory, *S*s were allowed free access to ad-lib food and water. The *S*s were then placed on a 12-gm. daily food-deprivation schedule, with water continuously available. The deprivation schedule was established 7 days before the start of the experiment. During the 3 days before the start of the experiment, each *S* was handled individually for 3–5 min. daily. Two days of pretraining preceded the experiment proper. On the first day all *S*s received 2 reinforced trials, and on the second day they received 4 continuously reinforced trials. The food cup in the goal box was baited on reinforced trials throughout the experiment with 2 1-cm.

Purina Hog Starter pellets (approximately 90 mg. each).

Two groups received 66% reinforcement, 17% nonreinforcement, and 17% punishment, and an additional group received 100% reinforcement. In Group NR, all nonreinforced trials were followed by reinforced trials, and punished trials were never followed by reinforced trials. In Group PR, all punished trials were followed by reinforcement, and nonreinforced trials were never followed by reinforcement. Group RR received 100% reinforcement throughout training. Punishment was administered immediately after *S* broke the final photobeam. The goal box was not baited on punished trials, and *S*s were removed from the goal box following punishment. The intensity of punishment was gradually increased from .3 ma. to .5 ma. in .1-ma. increments during every fifth day of training. On nonreinforced trials, *S*s were confined in the goal box for 15 sec.

Acquisition training lasted 15 days with 4 trials/day. The rats were run in squads of 6, with a 15-sec. intertrial interval. In order to prevent *S*s from forming a pattern discrimination, 3 different sequences were used during acquisition, each being used a total of 5 times. The 3 sequences of N, R, and P trials for Group NR were NRRR, RRRP, and NRRP. For Group PR, the sequences were RRRN, PRRR, and PRRN. Following acquisition, half of the *S*s in each group received punished extinction and the other half received unpunished extinction. Testing consisted of 20 trials in 5 days, 4 trials/day.

Results

Acquisition. Asymptotic performance was evaluated by analyzing the mean daily running speeds over the last 5 days of acquisition (20 trials). A 3 (Group) × 2 (Response Decrement) × 5 (Days) repeated-measures analysis of variance indicated nondifferential group performance as a function of training in start, F (2, 54) = 1.76, $p > .05$; in run, F (2, 54) = .38, $p > .05$; and in total, F (2, 54) = 2.54, $p > .05$. The main effect of group did account for a significant portion of the variance in the goal measure, F (2, 54) = 9.64, $p < .01$. Post hoc comparisons (all comparisons reported in this and the subsequent experiment used the Scheffé correction procedure for post hoc comparisons) indicated that Group RR was superior to both Group PR and Group NR ($p < .01$). Unlike the acquisition data reported by Capaldi and Levy (1972), Groups PR and NR did not differ from each other. The response decrement variable (extinction vs. punished extinction), which was a dummy variable for acquisition, was nonsignificant in all measures (all Fs < 1). The main effect of days was significant in start, F (4, 216) = 6.10, $p < .01$; in goal, F (4, 216) = 26.02, $p < .01$; and in total, F (4, 216) = 8.68, $p < .01$; but not in the run measure, F (4, 216) = 2.16, $p > .05$. None of the interactions in the analysis were significant. As the analyses indicated, very little response suppression was observed in Groups NR and PR relative to the continuously reinforced controls. It should be mentioned that at no time did any *S*s in Groups NR or PR evidence patterning. Mean speeds across the last 5 days of acquisition are shown as Point A in Figure 1.

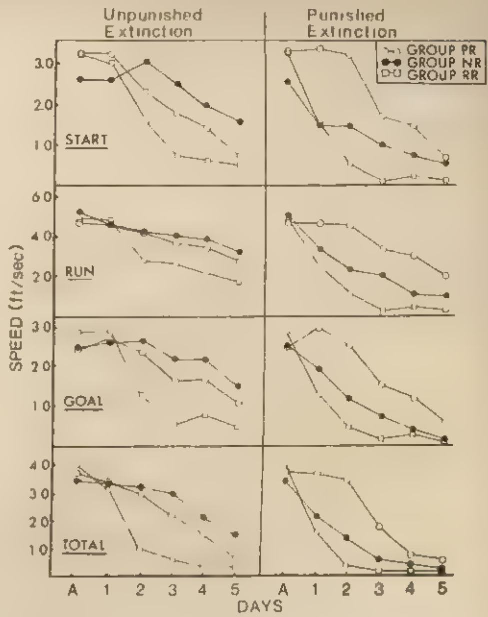

FIGURE 1. Mean running speeds for the last day of acquisition (A) and 5 days of punished and unpunished extinction for all runway measures.

Response decrement. A 3 (Groups) × 2 (Response Decrement) × 5 (Days) analysis on the mean daily speeds indicated a significant main effect for groups in start, F (2, 54) = 19.47, $p < .01$; in run, F (2, 54) = 46.21, $p < .01$; in goal, F (2, 54) = 31.87, $p < .01$; and in total, F (2, 54) = 50.59, $p < .01$. Post hoc comparisons

showed that PR groups were superior to NR groups, and both were superior to RR groups ($p < .01$ in all cases). The response decrement main effect (punished extinction vs. unpunished extinction) accounted for a significant portion of the variance in all sections of the alley, the smallest F being 22.15 in start ($df = 1, 54$ in all cases). This finding reflects the fact that punished extinction produced greater response decrements than unpunished extinction. The most important finding was the significant Group × Response Decrement interaction in start, $F(2, 54) = 8.20$, $p < .01$; in run, $F(2, 54) = 11.12$, $p < .01$; in goal, $F(2, 54) = 10.38$, $p < .01$; and in total, $F(2, 54) = 14.40$, $p < .01$. Post hoc comparisons indicated that Group PR was superior to Group NR in punished extinction in all measures. On the other hand, Group NR was superior to Group PR in unpunished extinction in all measures ($p < .01$ in all cases) except run, where the 2 groups did not differ from each other. Of course, Group RR was inferior to all other groups, regardless of the response-decrement procedure employed. It is notable that Group PR performed as well in punished extinction as in unpunished extinction in some sections of the alley. In start and total measures, performance to the 2 response-decrement procedures was nondifferential; however, performance in the run and goal sections was better in unpunished extinction than in punished extinction ($p < .05$ in both cases). Both Group NR and Group RR were superior in unpunished extinction relative to punished extinction. Of course, the days main effect was highly significant in all sections. The Fs for start, run, goal, and total were 55.16, 82.49, 91.29, and 124.34, respectively ($df = 4, 216$ in all cases). The greatest decrement was noted in the goal section and the least in start, with run showing intermediate suppression. Finally, the Groups × Days interaction was significant in all sections, with the smallest F being in run, $F(8, 216) = 3.33$, $p < .01$. This interaction is indicative that the groups extinguished at different rates. These effects for each of the alley segments across days are shown in Figure 1.

Discussion

The acquisition data repo[illegible]d here differ somewhat from previous res[illegible]n (Campbell et al., in press; Capaldi & Le[illegible] 1972) in that suppression, which was very [illegible]ght, was observed only in the goal section [illegible] in both of the studies mentioned, suppressio[illegible] was substantial during training, and th[illegible] [illegible] suppression was dependent on th[illegible] [illegible] sequential transitions experienced. It is [illegible]ely that the lack of suppression in this exp[illegible]ment was due to the fact that punishment w[illegible] administered on a sparse schedule (i.e., on[illegible] 17% of the trials were punished). In ad[illegible] [illegible] punishment was given on every thi[illegible] [illegible] training. It is notable that suppression [illegible] observed occurred in the goal section. [illegible], that segment of the instrumental res[illegible] chain occurring in the closest tempor[illegible] and spatial proximity to punishment wa[illegible] suppressed whereas earlier segments of the [illegible]ponse were not. Evidence from a number [illegible] experiments (Campbell & Meyer, 1971; Cap[illegible]di & Levy, 1972; Capaldi & Ziff, 1969) p[illegible] support for the notion that mildly ave[illegible] stimuli in the goal box produce differe[illegible] between groups in the goal section, whereas more intense aversive stimuli produce group differences in the earlier segments of the runway. Presumably, differences in the start and run sections of the alley between the punished and unpunished groups would have been observed if punishment intensity and/or density had been increased in the present experiment.

The response-decrement results obtained in the present experiment reflect the powerful influence of "sequence" in determining response persistence. More importantly, response persistence was shown to be a function of the interaction between the type of sequences used in training and the kind of response-decrement procedure used in testing. Consistent with this prediction, it was found that Group PR was superior to Group NR in punished extinction, while the reverse was true in unpunished extinction. Thus, P–R transitions increase response persistence relative to N–R transitions when testing is done with punishment-related stimuli. Conversely, N–R transitions provide for greater persistence than P–R transitions when testing occurs with nonreinforcement-related stimuli. This interaction is predicted by sequential theory, following the assumption that persistence to response-decrement testing is increased by the similarity between memory stimuli conditioned to the

instrumental response during training and the stimuli presented during testing (i.e., stimulus-generalization decrement). Thus, both Group PR and Group NR performed better when they were tested with stimuli that had been conditioned to the instrumental response during training than when they were tested with stimuli not directly conditioned. It is noteworthy that, in a similar experiment, Campbell et al. (in press) found that *S*s trained with both N–R and P–R transitions were as persistent in unpunished extinction as *S*s trained only with N–R transitions. A comparison of the present results with those reported by Campbell et al. illustrates how subtle variations in "sequence" can dramatically alter performance.

It is notable that Group PR was markedly superior to Group NR in punished extinction, but the superiority of Group NR over Group PR was less pronounced in unpunished extinction. In fact, the run measure did not reflect differential group performance in unpunished extinction. This finding may be interpreted by considering that punishment was administered on nonreinforced trials. For Group PR, subsequent reinforced trials may have resulted in the conditioning of a compound memory stimulus consisting of both nonreinforcement and punishment elements (S^N plus S^P) to R_I. Thus, Group PR was provided with some degree of persistence to nonreinforcement-related stimuli as well as to punishment-related stimuli. This analysis also provides an explanation for the group main effect finding which showed Group PR to be more persistent than Group NR when the data were collapsed across the response-decrement variable.

Experiment II

Although the data from Experiment I clearly reflect the powerful influence of sequential manipulations in determining response persistence, it was felt that an additional experiment would provide more information on the interaction between training sequence and response-decrement procedure.

Thus, 2 groups were given training similar to that experienced by Groups NR and PR in Experiment I. Following training, all *S*s experienced a 3-phase response-decrement test, in which a period of punished extinction was administered between 2 periods of unpunished extinction.

Due to the brevity of the initial phase, it was hypothesized that performance would be nondifferential. In the second phase (punished extinction) it was hypothesized that, due to the reinstatement of punishment-related cues, Group PR would be superior to Group NR. Finally, in the third phase of the test it was hypothesized that Group NR might be superior to Group PR. The third phase (unpunished extinction) was included to determine whether or not the reinstatement of S^N would produce increased performance in Group NR.

Method

Subjects. The *S*s were 20 experimentally naive male albino rats of the Sprague-Dawley strain, purchased from the Holtzman Co. They were housed individually and were approximately 70 days old at the start of the experiment. The *S*s were randomly assigned to 1 of 2 experimental groups ($n = 10$/group).

Apparatus. The apparatus was identical to that utilized in Experiment I.

Procedure. Acquisition training was carried out in the same manner as in Experiment I, with the following exceptions: (*a*) training was extended to 112 trials, 4 trials/day for 28 days, and (*b*) several additional sequences were included to prevent *S*s from forming a pattern discrimination. The additional sequences for Group NR were RRNR and RNRP. For Group PR, the additional sequences were RRPR and RPRN. The percentage of nonreinforcement–reinforcement–punishment events was exactly the same as in Experiment I. Furthermore, it should be noted that on any given day, all *S*s experienced the same number of each kind of goal-box event.

Response-decrement testing consisted of 3 phases: unpunished extinction, punished extinction, and unpunished extinction. Testing consisted of 24 trials, 4 trials/day for 6 days. Each of the 3 phases lasted for 2 days.

Results

Acquisition. The mean daily running speeds during the last 5 days of acquisition were analyzed by means of a 2 (Group) × 5 (Days) repeated measures analysis of variance. The differences between Groups NR and PR were negligible at the end of acquisition training in start, goal, and total measures (*F*s < 1), although there was a

nonsignificant trend for Group PR to be superior to Group NR in the run section, F (1, 18) = 3.58, $p > .05$. The days main effect was significant, indicating a general increase in speeds, F (4, 72) = 5.09, $p < .01$; in run, F (4, 72) = 10.19, $p < .01$; in goal, F (4, 72) = 4.83, $p < .01$; in total, but not in start, F (4, 72) = 1.88, $p > .05$. Finally, the interaction did not approach significance in any of the runway sections, the largest F being in total, F (4, 72) = 1.69, $p > .05$.

Response decrement: Phase 1 (unpunished extinction). A 2 (Group) × 2 (Days) repeated measures analysis of variance, performed on the mean daily running speeds, indicated a nonsignificant main effect for groups in all runway measures: Fs = .01, .69, 1.06, and .55 in start, run, goal, and total sections, respectively (df = 1, 18 in all cases). The days main effect was significant at the .01 level or better in all measures, the smallest F being 9.23 in start (df = 1, 18). The Groups × Days interaction was negligible in all runway measures (Fs < 1 in most sections). Thus, the first phase of the response-decrement test produced a nondifferential decline in response speed (i.e., both groups were running more slowly than in aquisition, but they were not different from each other).

Response decrement: Phase 2 (punished extinction). A 2 (Group) × 2 (Days) analysis indicated a significant main effect for groups in start, F (1, 18) = 5.46, $p < .05$; in run, F (1, 18) = 11.02, $p < .01$; in goal, F (1, 18) = 5.93, $p < .05$; and in total, F (1, 18) = 8.06, $p < .01$. The days main effect was significant in all segments of the runway with the smallest F being in start, F (1, 18) = 39.03, $p < .01$. The Group × Days interaction did not account for a significant portion of the variance in any of the runway sections. The major finding was that Group PR was statistically superior to Group NR in punished extinction, consistent with the finding in Experiment I.

Response decrement: Phase 3 (unpunished extinction). A 2 (Groups) × 2 (Days) analysis on the mean daily running speeds (8 trials) revealed a significant group main effect in run, F (1, 18) = 4.72, $p < .05$; in goal, F (1, 18) = 7.19, $p < .05$; and in total, F (1, 18) = 4.89, $p < .05$; but not in start, F (1, 18) = 3.32, $p > .05$. Group PR maintained its superiority over Group NR despite the fact that no reinforcement stimuli were reinstated in the goal box without punishment. The days main effect accounted for a significant portion of the variance only in the start measure, F (1, 18) = 12.15, $p < .01$. This indicates that *S*s had reached asymptotic extinction in all runway segments except for the start measure, in which some decline was still observed. The Group × Days interaction was negligible in all runway sections (most Fs < 1).

Phase 2 trial analysis. In order to examine Phase II performance more closely, a 2 (Group) × 4 (Trials) analysis was performed on the running speeds for the 4 punished trials on each of the 2 days of punished extinction. The analysis on the first day of punished extinction showed that the group main effect was significant in all runway measures: in start, F (1, 18) = 5.67, $p < .05$; in run, F (1, 18) = 13.35, $p < .01$; in goal, F (1, 18) = 8.36, $p < .01$; and in total, F (1, 18) = 10.19, $p < .01$. The Group × Trials interaction also accounted for a significant portion of the variance in start, F (3, 54) = 2.92, $p < .05$; in run, F (3, 54) = 3.13, $p < .05$; and in total, F (3, 54) = 5.87, $p < .01$; but not in goal F (3, 54) = 1.29, $p > .05$. Post hoc comparisons indicated that the performance of the 2 groups on the first punished trial was nondifferential. However, Group PR was superior to Group NR on the second trial (all ps < .01) and all succeeding trials. Thus the superiority of Group PR over Group NR was evidenced after the administration of only one punished trial. Of course, the trials main effect was significant in all runway measures. On the second day of punished extinction, a pattern of results similar to the first day was observed except that performance was slower and therefore the magnitude of the group differences was smaller. The group main effect was reliable in start, F (1, 18) = 4.56, $p < .05$, and in run, F (1, 18) = 7.81, $p < .05$; but not in goal, F (1, 18) =

3.49, $p > .05$, or total, $F(1, 18) = 4.19$, $p > .05$. The Group $\times$ Trials interaction was statistically significant in start, $F(3, 54) = 4.04$, $p < .05$; in run, $F(3, 54) = 7.14$, $p < .01$; and in total, $F(3, 54) = 2.91$, $p < .05$; but not in goal, $F(3, 54) = 2.56$, $p > .05$. Appropriate post hoc comparisons (on start, run, and total data) indicated that group performance was nondifferential on the first punished trial: however, by the second trial, Group PR was superior to Group NR ($p < .01$ in all cases except goal). The trial-by-trial performance of the groups during the 2 days of punished extinction is shown in Figure 2. An inspection of the graphs on the second day of punished extinction indicates that Group PR actually ran faster on the second trial than on the first. This effect was statistically reliable in both the start and run sections ($p < .05$ and $p < .01$, respectively). On the other hand, it can be seen that Group NR ran reliably slower on the second trial of both punished extinction days ($p < .01$ in all cases). A related finding was that the groups performed nondifferentially on the first trial of each day, thereby indicating that spontaneous recovery was not differently affected by the treatment variables.

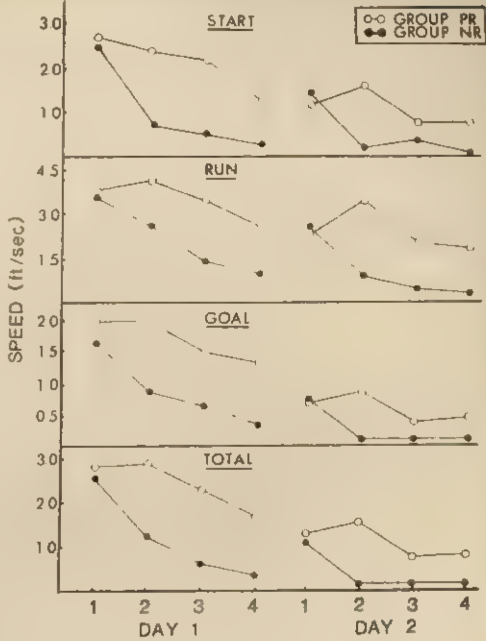

FIGURE 2. Mean running speeds for the 2 days of punished extinction for all runway measures.

Discussion

The response-decrement findings in Experiment II are generally consistent with the results of Experiment I. Following a block of unpunished extinction trials (Phase 1) in which performance was nondifferential, the sudden introduction of punishment produced dramatic between-groups performance differences (Phase 2). These differences were nonexistent on the first punished trial, but appeared in robust form on following trials. The sudden superiority of Group PR over Group NR in punished extinction indicates that stimulus control (i.e., the capacity of S^P to occasion R_I) of punished reactions is maintained through a block of unpunished extinction trials.

In contrast, the data obtained in the final phase of unpunished extinction did not conform to prediction. It was hypothesized that the reinstatement of S^N would result in increased performance for Group NR and decreased performance for Group PR. This hypothesized interaction did not occur; rather, both groups seemed to reach asymptotic extinction performance with Group PR still running significantly faster than Group NR. Several possibilities may be considered to account for the Phase 3 data. First, it is possible that proactive interference occasioned by Phase 2 punishment resulted in the disruption of the S^N–R_I association for Group NR. This is a plausible assumption, but it is not immediately clear why unpunished extinction (Phase 1) did not proactively interfere with Phase 2 performance for Group PR. A second possibility to account for the poor performance of Group NR in Phase 3 is that nonreinforcement memory stimuli are simply not as distinctive as punishment memory stimuli, and therefore stimulus control established with S^N dissipates or is disrupted more readily than stimulus control established with S^P. Finally, it is possible that Phase 3 performance merely reflects *S*'s ability to recover from the effects of response-contingent punishment. Group PR had reinforcement associated with the aftereffect of punishment during training, whereas Group NR did not; consequently S^P may have been psychologically more intense for the latter *Ss*. If S^P was a more "intense"

event for Group NR relative to Group PR, poorer recovery for the latter group would be expected. There is evidence (Boe & Church, 1967) that recovery from punishment does not occur (when punishment is delivered at the beginning of extinction) at a wide range of punishment intensities, with the extent of suppression being inversely related to punishment intensity. In summary, it is possible that a combination of the factors mentioned is responsible for the poor performance exhibited by Group NR in Phase 3.

General Discussion

These experiments suggest that the trial sequencing of partial-punishment partial-reinforcement training controls performance during response-decrement testing. Furthermore, the level of performance depends not only on the trial sequence of nonreinforcement–reinforcement–punishment events in training, but also upon the kind of response-decrement procedure that is used during testing. These effects were demonstrated using both a between-*Ss* and a within-*Ss* response-decrement procedure.

These data confirm and extend the results of Campbell et al. (in press) and Capaldi and Levy (1972) and lend further support to the notion that sequence is a crucial determinant of response persistence. It appears that P–R transitions function in a manner analogous to N–R transitions. However, the theoretical similarity between nonreinforcement and punishment could be extended even further if effects analogous to those obtained in partial-reinforcement–extinction situations were demonstrated using punishment.

VERBAL CONTEXT SHIFTS AND FREE RECALL [1]

ALAN S. BROWN AND BENTON J. UNDERWOOD [2]

Northwestern University

The number of different stimuli (1, 2, 3, 4, 9, 18, or 36) associated with 36 response terms was manipulated as a means of simulating variation in contextual shifts in free recall. Recall was inversely related and pair recognition directly related to number of different stimuli. When response terms with the same stimulus terms were blocked within a list, performance generally decreased within blocks. When the pairs were unblocked, evidence for unlearning of the early pairs was found. The interpretation of unlearning was supported by the further finding that spontaneous recovery of the initial items occurred over a 20-min. interval. Insofar as the present procedures simulated context shifts realistically, it must be concluded that a complex set of phenomena emerge as context shifts in free recall.

Investigators representing a wide range of theoretical persuasions have found it convenient, if not necessary, to invoke contextual stimuli to account for at least some of the responses produced in single-trial free recall. Contextual stimuli are usually said to be represented by the characteristics of the physical environment or by *S*'s emotional and cognitive activity, the latter including the implicit verbal responses which may be produced by the words presented for learning. Direct evidence on the role of contextual stimuli in memory has sometimes been produced (e.g., Turvey & Egan, 1969), but there is nearly a complete lack of systematic studies on the topic for free-recall learning. The original conception of the first study to be reported here viewed the conditions as being ones which would provide systematic evidence on the role of context. As will be seen, they may also be viewed as dealing with other related phenomena.

Consider a situation in which *S* is presented a paired-associate list for one trial and is then asked to recall only the response terms. The formal stimulus terms may be conceived of as contextual stimuli, each serving as a unique context for its response term. Like contextual stimuli, the stimulus terms do not have to be overtly produced. If they serve a role in the recall of the response terms, their systematic status is essentially the same as that attributed to context cues except that, in this case, they are under experimental control. If *S* can recall (to himself) a stimulus term, and if an association has been established between it and the response term, the response term will be produced. Of course, the critical question is sidestepped, for an appeal to some other context would be necessary to explain how the stimulus term was recalled. Only if the contextual stimuli are always present (as would be true for the physical properties of the room) could this problem be avoided. Any notion of a nonstatic context—a shifting context or a series of successive contexts—requires that in some way that context be reinstated (remembered) if it is to serve as an effective cue for recall.

Although the present experiment does not resolve the basic issue, it proceeds on the assumption that it is quite possible to vary the likelihood with which context stimuli will be recalled. In the first experiment, *S*s were presented a paired-associate list of 36 pairs. There were 36 different stimulus terms at one extreme, and in successive conditions there were fewer and fewer different stimulus terms, each being paired with more than one response term, until at the other extreme there was a single stimulus term paired with 36 different response terms. The pairs with common

[1] The authors acknowledge with gratitude the critical appraisal of this report by John J. Shaughnessy.

[2] Requests for reprints should be sent to Benton J. Underwood, Department of Psychology, Northwestern University, Evanston, Illinois 60201.

stimulus terms always occurred in blocks. It might be assumed that contextual shifts occur on the study trial of a long free-recall list of single words. The present manipulations were intended to simulate such shifts; each change in a stimulus term was likened to a context shift. Furthermore, it can be seen that as the number of context shifts decreases, the frequency with which each stimulus term (context) is presented increases. Thereby, the probability that the stimulus term will be recalled increases.

If the formal stimulus terms are to simulate contextual cues in free recall, 2 learning conditions must be met. First, *S* must know that he will be expected to recall the response terms without the stimulus terms (context) present. Second, at the same time, he must know that he will also be held responsible for associating the response terms with the context. Therefore, in addition to being instructed that response-term recall would be required, *S* was told that his knowledge of the pairings would be tested by a recognition procedure.

If the procedures as described are a reasonable representation of context variation, it follows that context changes within a single free-recall study trial could bring into play a number of phenomena, listed below.

1. When more than one response term is paired with a single stimulus term, an A-B, A-C paradigm is set up within the list. This could produce either or both of 2 outcomes. First, the earlier learned pairs within a block could produce negative transfer in attempts to learn later pairs. Second, and working in the opposite direction, attempts to learn later pairs in a block could produce unlearning of earlier pairs. Furthermore, the magnitude of the effects ought to vary as a function of the number of different response terms paired with a common stimulus term.

2. One could view each block of pairs with the same stimulus term as a list. Thus, when the same stimulus term occurred with 12 different response terms there would be 3 different lists. Since retroactive inhibition has been shown for free-recall lists, a compar[illegible] phenomenon may emerge within the l[illegible]

3. An increase in the [illegible] of different stimuli within the list m[illegible] reduce the interference effects resulti[illegible]om the A-B, A-C paradigm but, at the [illegible] time, increase the memory load [illegible] of different words) for *S*.

These potential com[illegible] factors might have recommended [illegible] research not be undertaken. Ou[illegible]stence resulted from the belief tha[illegible] regarding contextual stimuli cannot [illegible] these complexities, so we chose to acc[illegible]hem in the initial experiment. Furthermore, in the analysis of the data, attem[illegible] have been made to determine if the a[illegible]mentioned interference effects were in [illegible] operating during the single study tria[illegible]

Experiment I

Method

The *S*s were given a single study [illegible] 36-pair list prior to being tested. Before [illegible]t was presented, they were told that their [illegible] would be tested in 2 ways. First, resp[illegible] term recall would be required; and second, a fo[illegible]d-choice recognition test would be given, in whic[illegible]ets of 2 pairs would be shown with the request to choose the correct pair (the pair presented on the study trial) in each set. Four study-test trials were used. Half of the *S*s were tested in each of the following orders: recall, recognition, recognition, recall; and recognition, recall, recall, recognition. The *S* did not know which test he would be given for a trial until after the study trial. The major interest was in the memory for the items after the first trial. Analysis of scores beyond the first trial has provided no useful information beyond that given by the first trial, so that all evidence to be presented is derived from the first-trial performance.

Lists. The 7 lists were constructed from 36 3-letter words of minimal letter duplication and from 36 2-syllable words having concreteness ratings of 6.0 or higher in the Paivio, Yuille, and Madigan tables (1968). The 3-letter words served as stimulus terms, the 2-syllable words as response terms. The instructions prior to learning included illustrations of both types of words (stimulus terms and response terms) so that *S* knew what to expect on the 2 types of retention tests.

The 7 lists represented the context manipulation, and these conditions will be designated by the number of stimulus terms used in the lists. For Condition 1, a single stimulus term was used, so it was essentially like a true free-recall list in that the stimulus terms could not be used as a differential

cue. In successive lists there were 2, 3, 4, 9, 18, and 36 different stimulus terms. For Condition 36, the 36 3-letter words and the 36 2-syllable words were paired randomly. When the number of stimulus terms was less than 36, they were chosen randomly from the 36 and paired randomly with the response terms, subject to the restriction that each was paired an equal number of times. Response terms paired with a common stimulus term were blocked within the list. Thus, in Condition 9, for example, there were 9 blocks of 4 pairs each, with the same stimulus term used within each block. The ordering of the blocks was random.

Procedure and testing. The data were collected by a group procedure. Prior to testing, each group was assigned randomly to 1 of the 7 lists. Within each group, the recognition test and the recall test were assigned randomly for the first trial after the study phase. For the recall test *Ss* were simply asked to write down all of the response words (which had been identified in the instructions as the right-hand 2-syllable words). For the recognition test, *Ss* were given a test sheet on which there were 36 sets of 2 pairs each, both pairs in each set having the same response term but a different stimulus term. The *Ss* marked the correct pair in a blank provided for this purpose. Both stimulus terms were always from the list. In Condition 2 there were only 2 stimulus terms, so these occurred in all pairs. For all other conditions, the incorrect stimulus term was chosen randomly, subject to the restriction that it was not used a second time until all other stimulus terms had been used once. The ordering of the sets of pairs on the recognition test sheet was random with respect to the order of the pairs on the study trial.

The pairs were presented for study at a 4.5-sec. rate. Approximately 3.5 min. were allowed for the test period. Small groups of *Ss* were tested until each condition had a minimum of 20 *Ss* each. Seven of these groups of 20 *Ss* had been tested for recall on the initial trial, 6 for recognition. The list designated Condition 1, in which only one stimulus terms was used, could not be administered as a recognition test in a meaningful manner. The *Ss* given this list had 4 successive recall trials.

Results

Response-term recall. The percentages of items recalled for each of the seven conditions are plotted in Figure 1. The base line is described as the log of the number of different stimuli involved in the 7 lists. Thus, the number of different contextual changes increases as the number of different stimulus terms increases. In general, recall decreased as the number of contextual stimuli increased, but the relationship is by no means a regular one. The differences among the recalls of the 7 groups are

FIG. 1. Response-term recall as a function of number of different stimuli for the 36 response terms.

statistically significant, $F(6, 133) = 4.33$, $p < .01$. Performance under Conditions 3 and 4 is less than that for Condition 9. However, the statistical reliability of these differences, as well as of the difference between Conditions 1 and 2, cannot be demonstrated. For the moment then, it may be said that as the number of different stimulus terms increased, there was a decrease in the number of response terms recalled. Stated in another way, the relationship shows that as the number of different words presented (stimulus words plus response words) increased, recall decreased. This might be interpreted in terms of memory load, although the data to follow make it unlikely that this interpretation will suffice.

Position and block effects. Figure 2 provides an initial inspection of recall as related to the position of the item on the study trial. The 3 lines represent different portions of the list, viz., primacy (Items 1–6), recency (Items 31–36), and all items in the body of the list (Items 7–30). First, it can be seen that there was a general decrease in recall of items from the body of the list as the number of different stimulus terms increased. Next, there was a lack of primacy and recency effects for Conditions 3 and 4; that is, recall for the initial and final positions did not differ appreciably from recall of the items within the body of the list. All other conditions show primacy and recency effects, although

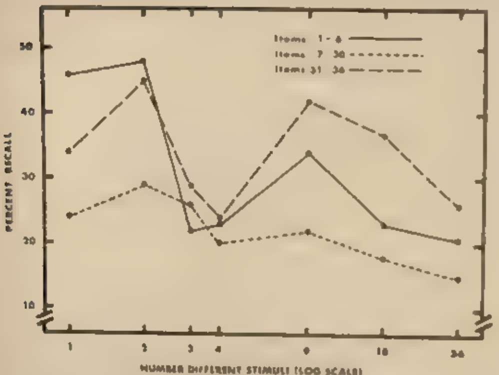

FIG. 2. Response-term recall as related to primacy (Items 1-6), recency (Item 31-36), and all other items (7-30), and to number of different stimuli.

the primacy effects are relatively slight for Conditions 18 and 36.

It was pointed out earlier that when *S* tries to learn response terms to a common stimulus, interference might occur. This in turn could lead to unlearning. If unlearning occurs, items early in a block having the same stimulus term should be more poorly recalled than items occurring late in the block. The data have been examined to see if they give any support to this notion. For Condition 18, where there were only 2 response terms for each stimulus term, recall of the first and second items (combined across the 18 blocks) was essentially equal. For Condition 9, very clear position effects were apparent within the blocks. The first item within the block showed the best recall, and the second was recalled better than the third and the fourth, the latter 2 being about equal. This finding provides no support for unlearning within blocks. Rather, it appears that each new stimulus term served to define a new rehearsal block, and as *S* proceeded through the 4-pair block, rehearsal fell most heavily on the first item in the block. In Condition 4 (9 response terms for each of 4 stimulus terms) there were no within-blocks differences of any consequence. The position effects within blocks were indistinguishable from those of Condition 1 when the latter was scored comparably.

For Conditions 2 and 3, the picture changes again. The percentages correct for 6 successive blocks of 6 items which have been determined for the 2 conditions. In Condition 3, each stimulus was paired with 12 response terms, hence each block with a single stimulus term consisted of 2 successive sixths. For Condition 2 the first 18 items had a common stimulus term and the second 18 had a different common stimulus term. Plotting in sixths means that the first 3 sixths had the same stimulus term, and the last 3 sixths the second stimulus term. Figure 3 shows that in Condition 3, performance increased for each successive block of 12 items and within each block, with the last 6 items recalled more poorly than the first 6. Thus, the within-blocks effects are much like those for Condition 9, and again, it would be concluded that no unlearning is apparent within blocks. For the first block of 18 items in Condition 2 there is a sharp decline across the 3 sixths. This is followed by a sharp increase as the stimulus term changes, followed again by a decrease, with what is apparently a recency effect in the final block. For both conditions represented in Figure 3, it becomes particularly clear that a change of stimulus context had a marked effect on the specific items recalled. Finally, for Condition 1, the recall by position was much like that for Condition 2 for the first 18 items, but, of course no marked increase in

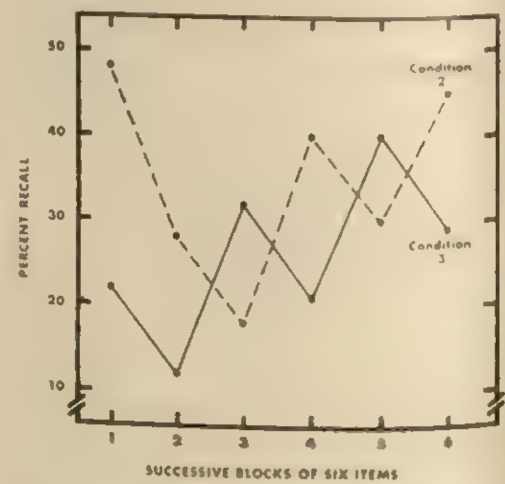

FIG. 3. Response-term recall for successive blocks of 6 items with 2 and 3 different stimulus terms.

recall occurred for the fourth sixth as was true for Condition 2.

Recognition. In the recognition tests, *S*s were required to choose between 2 pairs in 36 sets, one pair in each set being correct, the other incorrect. The percentages correct for the 6 conditions are shown in Figure 4. Unlike recall, recognition performance generally increased as the number of stimulus terms increased. The difference overall is statistically reliable, F (5, 114) $= 2.49$, $p < .05$, although the maximum difference is only about 10%.

Primacy effects, although small, were present in the recognition scores, but there were no recency effects. Furthermore, differences within blocks, so evident in several of the conditions for recall, were much less apparent in the recognition data. Correct decisions made on pairs in recognition might be expected to be correlated with the recall of the response terms of those pairs when summed across *S*s. For the 6 conditions, the product-moment correlations across the 36 items varied between .01 and .31. Although even the largest value is not significant by conventional standards, the fact that all 6 correlations were positive indicates a slight relationship, perhaps reflecting the common primacy effect found in both recall and recognition. In any event, these data indicate that knowledge of associations, as determined by recognition of appropriate pairing, holds little relationship to the recall of the response terms of those pairs.

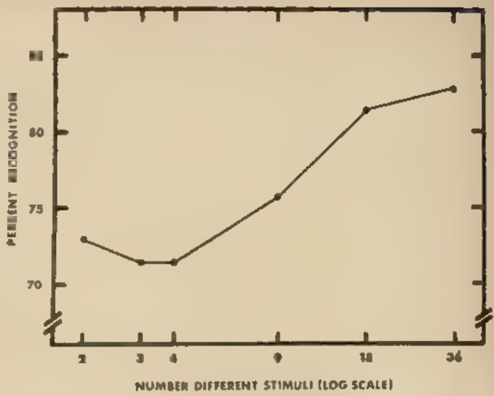

FIG. 4. Pair recognition as a function of number of different stimuli during the learning trial.

DISCUSSION

Discussion

As pointed out in the introduction, it had been expected that learning of the different lists would produce a rather complicated picture, and this expectation seems to have been realized. Yet evidence for within-lists interference produced by the A–B, A–C paradigm is not easy to identify. The recognition data do suggest that the fewer different response terms associated with a given stimulus term, the more intact the association. There was no support for the idea that unlearning might occur within blocks. Except for Condition 4, within-blocks differences were quite marked, with performance on the initial items in a block being better than on later items. One interpretation that has already been suggested is that the blocks, at least the smaller ones, provide a ready rehearsal set. This interpretation is not without some ambiguity, since the same type of effect would be expected if the early pairs interfered with the learning of the later pairs. However, as will be seen in Experiment II, it is likely that the interference component is relatively small.

For some lists (Figure 3) there was a sizeable increase in recall for each successive block. This could be interpreted as retroactive interference of later blocks on earlier blocks. Such interference would have to result from an A–B, C–D paradigm. This may not be plausible. An alternative interpretation is that the increase in recall across blocks simply represents differences in recall associated with retention intervals of different lengths.

Context can play a role in recall only if it is reinstated at the time of recall. There is little doubt that for the lists with relatively few stimulus terms, these terms could have been recalled. The number of response terms recalled was directly related to the likelihood that the stimulus terms could be recalled. Yet, it should be clear that there is no convincing evidence that recall of the response term was mediated by the recall of the stimulus term. So far as we can tell, there is no way to design an experiment to make such a determination directly. Although not reported above, clustering by stimulus terms occurred only in Conditions 9 and 18 in amounts greater than could be expected for clustering mediated by position alone (as determined from Condition 1). This makes it likely that stimulus-

term recall preceded response recall, but such a result does not demand this interpretation.

It is apparent that the complexity of the findings requires more analytical work if the processes associated with context shifts are to be untangled. Experiments II and III were viewed as first steps toward this untangling, with the focus being on the interference (and unlearning) for the within-lists A–B, A–C paradigm.

Experiment II

In Experiment II the A–B, A–C pairs have been unblocked. This was viewed as a means of breaking up, or at least minimizing, the possibility that common stimulus terms may be used to define rehearsal blocks. There were 3 lists, corresponding to those in Conditions 3, 4, and 9 in Experiment I. As a second variable, half of the *S*s were given the stimulus terms at the time of recall of the response terms, and half were given free recall of the response terms. All *S*s were instructed that they would be tested for response-term recall with and without the stimulus terms present. Thus, the instructions again met the 2 requirements believed necessary if the stimulus terms were to simulate contexts.

Method

The pairs used in Experiment I for Conditions 3, 4, and 9 were assigned randomly to positions in the list, subject only to the restriction that pairs with the same stimulus were not allowed to occupy adjacent positions. Three groups of 20 *S*s each were given response-term recall (as in Experiment I), and 3 additional groups of 20 *S*s each were given the stimulus terms on the recall sheet and were asked to pair the response terms with the appropriate stimulus terms. The *S*s in all groups were instructed that on successive trials they would be given both free recall and cued recall, the particular type of recall to be identified after the list had been presented for learning. As with Experiment I, trials beyond the first are not included in the present analysis, these extra trials being given merely to fulfill the obligation implied by the instructions. All other procedures were the same as those in Experiment I.

Results

Recall. The recall for the 6 groups varied between 17.2% and 23.9%. Mispaired responses for the cued condition were counted as correct. Neither condition, as defined by number of stimuli (F = [illegible]), nor cuing vs. noncuing ($F = 1.61$), was significant source of variance. An analysis of the free recall, which included the data from the 3 conditions in Experiment I, showed no statistical difference, although the lack of a difference is difficult to interpret as the 2 experiments were performed at different times in the school year.

Position and recall. There were no systematic differences in recall as a function of position of the items on the same trial between cued and free recall. Therefore, the data have been combined to evaluate the influence of input position on recall. Some general observations will be made initially. All 3 conditions showed marked primacy and recency effects, in contrast to Experiment I, where Conditions 3 and 4 showed little evidence of such effects. For the 3 conditions of Experiment II, primacy (Items 1–6) increased directly as number of stimulus terms increased, the values for recall being 28%, 35% and 45% for Conditions 3, 4, and 9, respectively. Recency effects (Items 30–36) were greater for Condition 3 than for Conditions 4 and 9, the values being 33%, 25%, and 26%, respectively. For items in the body of the list (7–30), recall decreased by 8% between Condition 3 (20%) and Condition 9 (12%), with Condition 4 intermediate.

The major interest was in the recall of successive response terms having the same stimulus term. There is no satisfactory way to remove the overall primacy and recency components from this analysis, since buffer items were not used. In fact, these effects should probably not be removed, since they may reflect in part the interference which is the focus of the analysis. The approach used was to examine recall as a function of position in the series of items having the same stimulus term and to compare this recall with the results of Experiment I. In Experiment I the pairs were blocked by stimulus terms, whereas in Experiment II the pairs with the same stimulus term were randomized throughout the 36 positions. The data were summed across different stimuli for the first occurrence of the stimulus terms,

the second occurrence, and so on. For Condition 9, each stimulus term occurred 4 times, hence each of the 4 positions was represented by the 9 different stimulus terms. For Condition 4 each stimulus term occurred 9 times, therefore, each of the 9 positions was represented by 4 different stimuli. Finally, for Condition 3, each stimulus occurred 12 times, so each of the 12 positions was represented by 3 different stimulus terms. The percentage recall was determined for each position in the sequence for each of the conditions of the 2 experiments. These values are plotted in Figure 5.

The first finding to be noted is the initial drop which occurs, this being greater for Experiment II than for Experiment I. The second finding of note is that following the initial drop, recall in Experiment II tended to increase across successive positions, whereas no such trend was apparent in Experiment I. This was particularly clear for Condition 3, where each stimulus occurred 12 times. The data for Condition 3 may be related to the plot for Experiment I, shown in Figure 3. For each of the thirds in Figure 3, the first 6 items within a block were better recalled than the second 6 items. This is reflected in Figure 5 for this condition, where recall for the first 6 positions (31%) is greater than recall for the last 6 positions (21%). In contrast, in Experiment II recall for the first 6 positions (20%) is less than for the last 6 positions (27%).

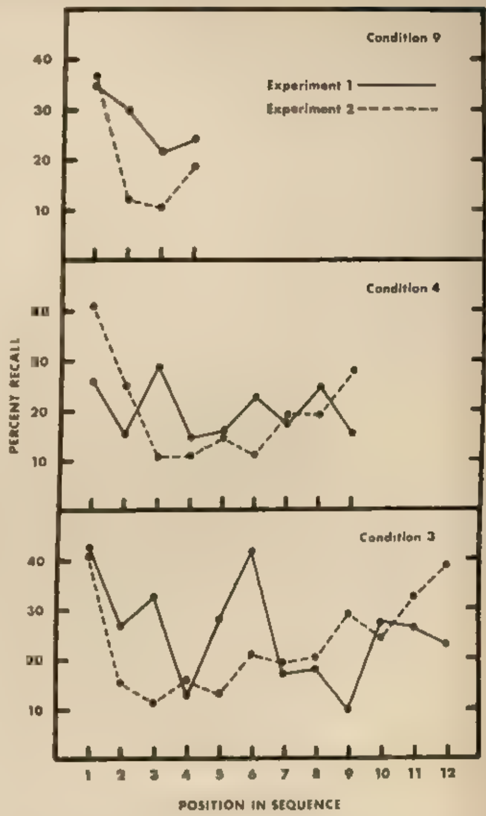

FIG. 5. Recall of response terms having the same stimulus terms as a function of position in the sequence. (In Experiment I the pairs with the same stimulus terms were blocked, while in Experiment II they were not. The conditions with 3, 4, and 9 different stimulus terms are represented in the 3 panels.)

Discussion

The results in Figure 5 for Experiment II suggest that unlearning occurred within the list when the same stimulus term was used for successive response terms. The first pair seems to be "protected" from unlearning, but beyond this there is a clear trend for each successive response term to be recalled better than the preceding ones, although the second position is somewhat ambiguous. Increasingly better recall with each successive stimulus should happen if each successive pairing produced more and more unlearning of previous items.

There are undoubtedly many other explanations in addition to unlearning which might be offered to account for the gradual increase in recall across positions (e.g., shorter retention intervals for later items). If unlearning is occurring, one expectation might be that absolute recall should have been better on, say, Positions 3 and 4 for Condition 9 than for Condition 3. This might be expected on the grounds that in the latter condition there were more successive items to produce unlearning than in the former. However, a complicating factor may arise from different amounts of retroactive interference between items with different stimuli. This possibility is greater in Condition 9 than in Condition 3.

When pairs are blocked, as in Experiment I, it seems likely that the blocking provides a ready rehearsal set which would counter unlearning, but which would lead to poorer recall for items late in the block than for those early

in the block. The purpose behind the unblocking in Experiment II was to remove the ready-made rehearsal blocks. It was believed that evidence for unlearning might be obtained under these circumstances. If unlearning did occur, as presumed in Experiment II, spontaneous recovery might be expected. Since unlearning is assumed to be greater for items in the initial positions, spontaneous recovery should be greater for the items in these positions than for items in the late positions sharing the same stimulus term. The purpose of Experiment III was to determine if spontaneous recovery could be detected in a delayed retention test.

Experiment III

There is no evidence as to the course of recovery over time following free-recall learning. Therefore, a 20-min. interval was chosen on the basis that spontaneous recovery has been observed within this range when the A–B, A–C paradigm holds between lists (e.g., Postman, Stark, & Henschel, 1969).

Method

A single list of pairs was used, this being the list identifying Condition 3 in the first 2 experiments. There were only 2 basic conditions, an immediate cued recall (the same as given in Experiment II), and for another group of *S*s, a cued recall after 20 min. Two random orders of the 36 pairs were employed, but since the results showed that [illegible] were equivalent, no further mention will be made of this factor. Each group was made up of 34 *S*s. The *S*s were instructed prior to the presentation of the list that they would be tested for recall and that the response terms were to be listed under the appropriate stimulus term. The *S*s were tested individually, and the words were presented at a [illegible] rate. Those *S*s given the 20-min. recall worked on a pyramid puzzle during the interval

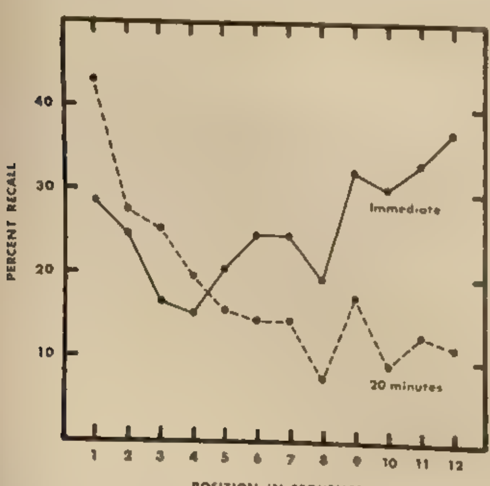

FIG. 6. Response-term recall as a function of the length of the retention interval (immediate or 20 min.) and position in sequences of response terms having the same stimulus term.

Results

The immediate recall was 25.4%, slightly higher than that for the comparable condition in Experiment II (23.9%). The group given recall after 20 min. produced 18.4% of the response terms.

The critical data are shown in Figure 6. The plot corresponds to that for Figure 5. Looking first at the immediate recall, it can be seen that except for the 2 initial positions, the recall by position was much the same as in Experiment II and as displayed in the lower panel of Figure 5. Why the primacy effect was greater in Experiment II than in Experiment III is not known. Recall by position after 20 min. was quite different from the corresponding curve for immediate recall. For the 4 initial positions, recall was actually higher after 20 min. than on the immediate test. On all subsequent positions it was less. In short, the results are not unlike those to be expected if unlearning and spontaneous recovery occurred. The interaction between position and length of retention interval is highly reliable, F (11, 726) = 11.36, $p < .01$, using an arc sine transformation of the data. Evaluated independently, recall for the first 4 positions is statistically greater for the 20 min. group than for the immediate group, F (1, 66) = 4.01, $p < .05$.

If there is output interference and if *S*s in the 20-min. group gave priority to the recall of the early items, while those with immediate recall gave priority to the recall of items late in the list, the results shown in Figure 6 might be produced. However, an analysis showed no difference between output order for the 2 groups. The data appear to be consonant with the notion that spontaneous recovery occurred and that

this retarded the forgetting of items. The greatest retardation occurred early in the list, where the greatest amount of unlearning is presumed to have taken place. Taken at face value, the data indicate that recovery even occurred for the first pair in the sequences.

General Discussion

The procedures of the present experiments were intended to simulate context shifts or changes. In the first experiment, recall was inversely related to the number of context shifts, although this relationship was neither strong nor regular. Number of context shifts was directly related to number of different stimulus terms. The relationship between context shifts and recall may be complicated by internal interference when the same context serves as a stimulus term for more than one response term. The fact that recognition showed that the association between stimulus and response terms remained more stable with increasing numbers of stimulus terms suggests that interference may counteract to some extent the positive effect of a relatively few context stimuli. Nevertheless, the positive and negative factors which seem to be operating jointly to produce recall performance may be quite realistic and applicable when notions concerning the role which context plays in free-recall learning are advanced. This is to say, simplified theoretical notions of the role of multiple contexts may not be appropriate.

As a context shift occurred—as pairs with the same stimulus term were followed by a pair with a new stimulus term—performance on the initial pairs after the shift was markedly enhanced under some conditions. When the pairs of words with the same stimulus terms were randomized within the list rather than being blocked, the learning pattern within the sequence of response words with the same stimulus terms changed. It is possible conceptually to think of contexts, particularly internal contexts, which may be present for only one word, and then reoccur at a later point in the list for a new word. Experiment II simulated this reoccurring context. The evidence from this experiment was interpreted as showing unlearning for pairs having the same context, with the earlier occurring pairs being unlearned as a consequence of the occurrence of the later pairs. Experiment III gave some support to this interpretation by showing that spontaneous recovery of unlearned associations may occur over a retention interval. Such data again suggest that contextual stimuli may produce a rather complicated set of relationships.

DICHOTIC LISTENING AND SEQUENTIAL ASSOCIATIONS IN AUDITORY SHORT-TERM MEMORY [1]

CATHERINE G. PENNEY [2]

Memorial University of Newfoundland, St. John's, Newfoundland, Canada

Two experiments are reported in which a dichotic (bisensory) stimulus presentation was used. In one experiment, 4 stimulus pairs were presented in a trial, 2 dichotic pairs being alternated with 2 visual pairs. The preferred recall order was mode by mode when all words were to be recalled, and ear by ear for auditory words. In Experiment II, 8 words were presented in a trial, but 4 words, 2 auditory and 2 visual, were simultaneous. The *S* was instructed to recall either the word presented before or after the probe but in the same ear or same part of the screen, or the word presented at the same time and in the same modality as the probe. The results were interpreted as evidence for the existence of strong associations between successive auditory stimuli.

In dichotic listening, auditory stimuli are presented 2 at a time, one to each ear, and *S* is asked to recall. If *S* is not instructed to report the items in any particular order, he tends, at fast presentation rates, to report all those items presented to one ear and then those presented to the other ear (Broadbent, 1954, 1956). At slow rates, he generally reports the first pair of items, then the second pair, and then the third pair.

Broadbent (1958) interpreted this "ear-by-ear" order of report in terms of the difficulty of switching attention between channels of information. He hypothesized that a selective filter mechanism can be set to select 1 channel, distinguished on the basis of some physical characteristic, and to reject all other channels. Because of the time involved in switching channels, ear-by-ear order of report is more efficient at fast, but not at slow, presentation rates. Subsequent work has indicated that at least 1 main assumption of Broadbent's model, i.e., that only simple physical characteristics could be analyzed prior to the filter, is incorrect. Several studies (e.g., Gray & Wedderburn, 1960; Yntema & Trask, 1963) have indicated that meaningfulness of input items could define a channel, and that meaning therefore must be decoded prior to or at the level of the filter.

Yntema and Trask (1963) suggested that *S* can perceive both items presented simultaneously and can tag items according to either their meaning or ear of arrival at input. The presence of the tags provides *S* with a way to systematically retrieve the items. With homogeneous stimuli, ear of arrival provides the basis for output organization, but with distinct classes of stimuli, recall by stimulus type is apparently preferred. It is not clear, however, why time of arrival is not equally useful.

Contrary to Yntema and Trask (1963), Bryden's (1964) data show that in some cases meaning alone is not a sufficient basis for a retrieval plan. He presented highly associated pairs of words where 1 word of each pair was presented to each ear. At fast presentation rates of 2 pairs/sec, he found that *S*s preferred to recall in an ear-by-ear order and not, as might be expected from the findings of Yntema and

Trask, in the terms of the associated pairs. Whitmore (1972) presented words dichotically in such a way that if *S* reported items in temporal pairs, he would have a meaningful sentence. Without specific instructions to the contrary, *S*s tended to report in an ear-by-ear order. It seems that Yntema and Trask's retrieval explanation is not entirely adequate, as *S*s appear to freely report according to meaning only when the meaningfully related items are not simultaneous.

A further complication is presented by the work of Savin (1967) and Rollins, Everson, and Shurman (1972). When 2 digits are presented simultaneously over a loudspeaker and do not differ in their physical characteristics, *S* presumably has no basis on which to channelize the information. One would therefore expect the items to be recalled in pairs. However, Rollins et al. and Savin found that *S* still preferred to recall the items in a sequential order, that is, an item from the first pair, one from the second pair, and the remaining item from the first pair and the last item.

When, instead of the 2 ears, the sensory modalities of audition and vision define the channels used, the picture becomes even more complex. The *S*s prefer to recall 3 audiovisual pairs by modalities at fast presentation rates, and as pairs at slow rates (Madsen, Rollins, & Senf, 1970). Output by modalities also results in higher recall than output by pairs (Broadbent & Gregory, 1965).

However, other findings indicate that the dichotic and bisensory situations are not strictly analogous. In the bisensory analogue of the Yntema and Trask (1963) study, Madsen et al. (1970) found that recall by type of stimuli resulted in a low level of performance at both fast and slow presentation rates. Broadbent and Gregory (1965) also found that recall according to types was worse than recall by modalities. Moreover, when auditory stimuli are presented alternately to the 2 ears, *S*s have no difficulty in recalling them in their sequential order (Moray, 1960). This finding does not hold when stimuli are presented alternately to the ear and eye (Broadbent & Gregory, 1961).

Finally, in contrast with auditory studies, an examination of the visual analogue of dichotic listening shows that the channel-by-channel report is not a preferred output order for recall of simultaneous stimuli. When separate digits are presented to each eye (Sampson & Spong, 1961) or 2 superimposed digits are presented to both eyes (Schurman, Everson, & Rollins, 1972), the preferred recall order is in terms of temporal pairs. However, Schurman et al. showed that *S*s were equally accurate with a temporal-pairs or a sequential recall order.

In summary then, a channel-by-channel recall order is obtained with both a dichotic and bisensory stimulus presentation, but not with a visual presentation. The variables of type of stimulus material, associative relations between items, and whether items on the 2 channels are simultaneous or successive do not have similar effects on recall order for the dichotic and bisensory task. These findings suggest the need for further investigation of the differences between audition and vision as input channels. These differences were explored in the present experiments using a task that combines dichotic and bisensory presentation. In Experiment I, pairs of dichotic auditory stimuli were alternated with pairs of simultaneous visual stimuli, and *S* recalled either the auditory stimuli, the visual stimuli, or both. With this type of stimulus presentation, one would expect recall to be organized by modalities, with either a temporal-pairs organization within each modality, or no strong organization at all.

Experiment I

Method

Design. On each trial, 8 stimulus words were presented as 4 successive pairs. On half of the trials the first and third pairs were presented dichotically, while the second and fourth pairs were visual (AVAV). On the other trials, the order of the word pairs was visual, auditory, visual, auditory (VAVA). At the end of each list, a cue was presented, indicating 1 of 3 recall conditions: recall of all of the words, only the auditory, or only the visual.

For each of these recall conditions, the postlist cue was auditory on half of the trials and visual on the other half. The 12 treatment combinations (obtained by factorially varying the cue modality, the recall instruction, and the order of the auditory and visual word pairs) were presented in a random order within a session with the restriction that each condition was tested once in each block of 12 trials. There were 6 blocks of experimental trials, giving 6 replications of each treatment combination for each *S*. To ensure that the results obtained would not be limited to a specific set of stimuli, 2 different sets of stimulus material were constructed. Six *S*s were tested on each set.

Subjects. The *S*s were first-year male and female University of Toronto students who participated in psychology experiments for credit. All *S*s were native speakers of English, were aware of no hearing impairment, and had normal or corrected vision. Three male and 3 female *S*s were individually tested on each set of stimulus materials.

Stimulus material. For each set of stimulus materials, words were randomly selected without replacement from a pool of 1,430 1-syllable common English words of all grammatical classes. The visual words were typed on a roll of plain white computer paper and presented over closed-circuit television. To construct dichotic tapes, a male and a female graduate student were isolated in soundproof booths which contained a microphone and a device set by *E* to click at a .75-sec. rate. The speakers uttered the stimulus words in time with every second click, starting after 4 or 5 warning clicks. The clicks were recorded on the tape to provide *S* with a signal before the start of each trial. The auditory and visual stimuli were synchronized by means of a Uher diapilot and a Hunter timer. The timer caused a video control monitor to transmit the signal to *S*'s television monitor for .75 sec. Except when a stimulus was being shown, *S*'s screen was bright but blank. The postlist cue was timed to occur 1.5 sec. after the start of the last stimulus pair.

Procedure. The *S* was given a sheet of instructions that described the simultaneous presentation of 2 words in 1 sensory modality and the alternation of the 2 modalities. The single word at the end of each list served as a recall cue. This last word was *one*, *two*, or *three* and was presented either auditorily or visually. The *S* was instructed to ignore the modality of the cue but to attend to the number. *One* signaled recall of all words, *two* indicated only auditory words, and *three*, the visual words. The *S* could recall the words in any order and was instructed to guess when uncertain.

The *S*'s performance was monitored during 12 practice trials to ensure that the instructions were followed. If *S* experienced any difficulty, a few extra practice trials were given. No *S* was rejected for inability to do the task. After the practice trials, any questions pertaining to the procedure were answered, and the 72 experimental trials then followed.

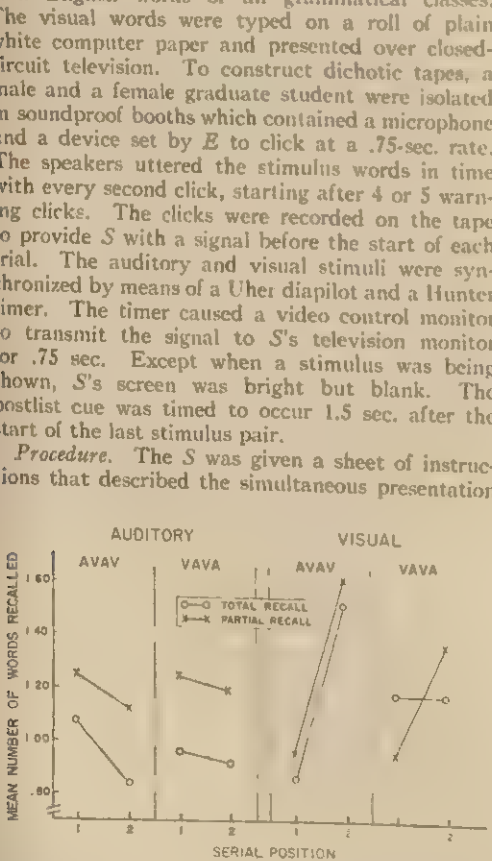

FIGURE 1. Recall of auditory and visual words as a function of serial position, modality order (A = auditory, V = visual), and type of recall trial.

Results

The criterion for scoring was lenient, and a different criterion was used for auditory and visual items. The reason for this was that, particularly for auditory items, there was a large number of what were possibly auditory perceptual errors. For example, *S* might report *block* or *blot* when the recorded word was *plot*. In an earlier experiment (Penney, 1973, Experiment I) with a similar stimulus presentation, a comparison of strict and lenient scoring criteria showed the pattern of results to be the same for both, with the main effect of using the lenient criterion being the raising of the level of recall of auditory items to approximately that of the visual items. The scoring criteria used were as follows. An auditory item was counted correct if the word spoken by *S* had no more than 2 incorrect phonemes. A visual word was counted correct if a possible spelling of *S*'s spoken recall contained no more than 1 incorrect, omitted, or transposed letter. For example *ace* would be accepted for *age* or *through* for *though*.

Figure 1 shows the mean number of words recalled from the pair as a function of serial position and modality. The separate panels are for the AVAV and VAVA presentation orders. The 2 curves in each panel represent the total- and partial-recall trials.

A $2 \times 2 \times 2 \times 2 \times 2 \times 2 \times 6$ analysis of variance was conducted with the follow-

ing factors: modality (auditory or visual), serial position within a modality (first or second pair), type of recall trial (total or partial), modality of the recall cue, order of the auditory and visual word pairs (AVAV or VAVA), set of stimulus materials, and *S*s. The dependent variable was the proportion of words recalled out of the 6 replications. As arc sine transformation was applied to these proportions (Murdock & Ogilvie, 1968).

Because of the different scoring criteria for auditory and visual items, a direct comparison of auditory and visual recall cannot be made. However, the interactions with presentation modality are independent of the main effect and can be interpreted. Figure 1 indicates that there is very little difference in recall as a function of serial position for auditory items. For visual stimuli, on the other hand, words from the second pair are generally recalled much better than those from the first pair. The serial-position effects are smaller for the VAVA order, with a flat curve in the total-recall condition. The Serial Position × Modality interaction was significant, $F\ (1, 5) = 20$, $p < .01$. These serial-position effects were large enough to cause the main effect of serial position to be statistically significant overall, $F\ (1, 5) = 8.9$, $p < .05$. There were, however, no reliable differences in recall of auditory and visual stimuli.

Recall of the visual words in the last serial position was lower in the VAVA condition than in the AVAV condition, but recall of the first pair was slightly better. Recall of auditory words did not seem to be affected by order. The Serial Position × Order interaction was significant, $F\ (1, 5) = 63$, $p < .005$, and the Serial Position × Modality × Order interaction was also significant, $F\ (1, 5) = 17$, $p < .01$.

Considerably more auditory words were recalled on partial-recall trials than on total-recall trials. For visual words, the effect of the type of recall trial was less marked. Overall, the main effect of the type of recall trial was highly significant, $F\ (1, 5) = 75$, $p < .005$, and the Modality × Type of Recall Trial interaction was marginally significant, $F\ (1, 5) = 6.6$, $p < .05$.

The total-recall trials were further examined to discover the order of recall of the different modalities. On 198 of 288 total-recall trials (68.8%), *S* recalled some words from both modalities and switched between modalities during output only once. On 44 of the remaining 90 trials, *S* recalled words from only 1 modality. Thus, there is still a strong preference for modality-by-modality recall even when auditory and visual stimuli are presented alternately (Broadbent & Gregory, 1965).

If only those total-recall trials on which *S* made exactly one modality switch are considered, 77.3% of the time *S* recalled the visual words first. The output priority given to visual items on total-recall trials explains why there is so little difference for visual stimuli on total- and partial-recall trials. The main effect of cue modality was not significant, nor was any interaction with cue modality.

The data of primary interest in this experiment are those concerning the order of recall of the auditory stimuli. Only partial-recall trials were examined. The first 2 words recalled were classified as having been presented at the same time, in the same place, or neither. For visual words, the "same-time" recall order occurred on 57.3% of the trials. A "same-place" output order was found on only 10.8% of trials. For auditory words, on the other hand, the first 2 words recalled had been presented to the same ear on 39.9% of the trials and at the same time on 21.2%. A sequential output order, in which the first 2 words recalled were presented to different ears and at different times, occurred on 18.1% of the trials. There is still a substantial preference for a sequential recall order over a temporal-pairs output order even when there are visual stimuli intervening between subsequent items presented to the same ear.

The finding of a preference for a sequential order of report in the present experiment would seem to pose a problem for Broadbent's (1958) model. A strategy of

attending to only one ear is unlikely, as on 131 of 288 auditory partial-recall trials, *S* was able to recall 3 or 4 auditory words. Of these trials, an ear-by-ear order of report occurred on 50.4%, a temporal-pairs order on 32.06%, and a sequential order on 17.56%.

In fact, many *Ss* reported that they tried to attend to the visual stimuli during presentation, as they found these more difficult to remember, and they certainly recalled them first on total-recall trials. If the auditory stimuli actually constituted the rejected channel, as *Ss*' introspective reports would suggest, the finding of an ear-by-ear report order is puzzling. The auditory items must stay in the sensory buffer while the visual information is passed through the limited-capacity system. When *S* is free to switch attention to the auditory mode, the most logical strategy would seem to be to process the 2 oldest items first.

It is clear that Broadbent's (1958) model, even in its revised form, has difficulty with these data. Equally, Yntema and Trask (1963) provided no explanation for the fact that *Ss* do not use time of arrival as a basis for organization. In the present experiment, time would seem to be as good as or better than ear of arrival as a basis for a retrieval plan. However, it may be that under different retrieval conditions, time of arrival could be an effective cue. In the second experiment, a partial- rather than a total-report procedure was used in order to see if *S*'s encoding and retrieval strategies were affected.

Experiment II

Most experiments on dichotic split-span memory have used a whole-report procedure and measured either the relative efficiency of, or *Ss* preference for, the ear-by-ear or temporal-pairs output order. In the second experiment, a partial-report technique was used, with *S* reporting only 1 word on each trial. The probe was either the word that had occurred at the same time as the to-be-remembered (TBR) word but in the other ear and voice (same-time probe) or a word that had been presented either before or after the TBR word in the same ear and voice (same-place probe). The requirement in earlier studies that *S* report every item on each trial may have necessitated, as Yntema and Trask (1963) suggested, some kind of tagging according to ear of arrival or stimulus type in order for *S* to have an organized retrieval plan. This tagging strategy may not be necessary when a probe technique is used. When *S* knows in advance of stimulus presentation whether he is to receive a same-time or same-place probe, he should be able to encode the items accordingly. Therefore, one would expect no difference in overall recall in the 2 probe conditions. The occurrence of any difference in recall would suggest that *Ss* are not always able to optimally encode information in this situation.

Method

Design. The second experiment involved a slight modification of the stimulus-presentation procedure used in Experiment I, in that the pairs of auditory and visual stimuli were presented simultaneously. The *S* was still presented with 8 words on each trial, but 4 rather than 2 words were presented at a time. The probe word was randomly selected from the 8 words with the restriction that in each block of 8 trials each of the 8 positions was tested once. There were 8 blocks of experimental trials and 2 blocks of practice trials, giving a total of 80 trials. All *Ss* were tested on both the same time (ST) and same place (SP) conditions, half receiving the ST condition first and half the SP. Two sets of stimulus material were used. Of those *Ss* receiving the ST condition first, half had Set A for this condition and Set B for the SP condition, while the remaining *Ss* had Set B for the ST condition and Set A for the SP condition. In this way, there was no confounding of probe conditions, stimulus set, and practice effects. The design is therefore a fully crossed factorial with position tested, replications (blocks), and instruction conditions varied within *Ss*, and presentation order of the instruction conditions and of the stimulus materials varied between *Ss*.

Subjects. Eight male and 8 female University of Toronto graduate students with normal or corrected vision and no known hearing defects were tested individually and were paid $4 for the 2 sessions.

Stimulus materials. Two sets of stimulus materials were used. For each set, 640 words were randomly selected from the word pool used in Experiment I. Recording of auditory stimuli and presentation of visual stimuli were similar to Ex-

periment I. The presentation rate was 1 set of 4 words per sec., with the actual presentation time of visual stimuli being .5 sec. Immediately following and in rhythm with the stimulus words, a random 1- or 2-digit number which *S* had to repeat was presented visually. This was necessary because a pilot study had indicated that recall of items in the second set of 4 words was very high. Following the number, the probe was presented in the same modality, and in the same voice and ear or to the same part of the screen as in the original presentation.

Procedure. The *S* read a sheet of typed instructions that described the stimulus presentation. Two sets of instructions were devised, one containing the ST instructions and the other the SP instructions. The ST instructions told *S* to recall the word presented in the same modality and at the same time as the probe word. The SP instructions asked for recall of the word presented in the same place as the probe. It was explained that "same place" referred to the same ear for auditory words and to the same part of the screen for visual words. The *S*s were further instructed that if they could not remember the required word, they were to report any other word from that trial. The *S* was given 16 practice trials, any questions about procedure were answered, and the 64 experimental trials then followed.

The same procedure was followed for the second session. When *S* entered the laboratory, he was given whichever instruction sheet he had not received the first day and instructed to read it carefully. He then received the 16 practice trials and 64 experimental trials, as on the first day.

Results

The following factors were included in the analysis of variance: serial position, modality, instructions, *S*s (nested under the following 2 factors), order of instruction conditions, and order of stimulus material. The dependent variable was the arc sine transformed proportion of words recalled out of the 8 replications (Murdock & Ogilvie, 1968).

Figure 2 shows the probability of recall as a function of serial position, presentation modality, and instruction condition. Serial position refers to the position of the recalled word, not to the position of the probe word. For both auditory and visual items, there is a large effect of serial position, with words in the second set being recalled at a higher level. The probabilities of recall of auditory words in the first and second serial positions were .473 and .617, respectively. For visual words, the

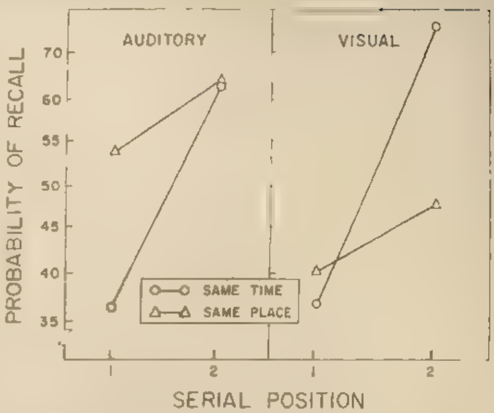

FIGURE 2. Probability of recall as a function of presentation modality (auditory or visual), serial position, and probe type.

corresponding probabilities were .391 and .586. The main effect of serial position was significant, F (1, 3) = 13.6, $p < .05$, as was the Serial Position × Modality interaction, F (1, 3) = 11.0, $p < .05$. The effect of serial position was slightly larger for visual items than for auditory.

The main effect of the instruction condition was not significant overall. However, the instructions did interact significantly with other variables. As Figure 2 indicates, the serial-position effects were quite different for the 2 instruction conditions. This Serial Position × Instructions interaction was confirmed by the analysis of variance, F (1, 3) = 12.6, $p < .05$. When SP instructions were given, the level of recall was only slightly better for the second serial position than for the first. With ST instructions, the difference between recall of words in the first and second serial positions was much larger.

The most interesting aspect of these data is the interaction between presentation modality and instructions. Compare recall of auditory and visual words under the ST instructions. For the first serial position, recall is about equal for auditory and visual items. For the second position, recall is slightly higher for visual items. The SP instructions result in quite a different picture. For both serial positions, recall of auditory items is clearly superior to that of the visual stimuli. The analysis

of variance indicated that the Modality × Instructions interaction was significant, $F(1, 3) = 18.7$, $p < .025$.

The direction of the Modality × Instructions interaction is consistent with the hypothesis of strong associations between successive and auditory stimuli. The forward and backward associations between auditory stimuli are clearly stronger than the corresponding associations for the visual stimuli. These sequential auditory associations are so strong that, for the first serial position at least, recall cued by a backward probe is actually better than that when a simultaneous stimulus is used as a retrieval cue (Duncan's range test, $p < .01$; Edwards, 1968).

That there is no difference in auditory recall for the 2 instruction conditions when the second serial position is tested does not weaken the argument. In the ST condition the item given as a probe was a recent item, whereas in the SP condition the probe was an earlier item. If there were retrieval difficulties involved in probe recognition, these should be greater for the SP probe. Recall of the tested item would then be slightly lower than it would be if the SP probe were as available as the ST probe.

The critical comparison, however, is between auditory and visual presentation under the SP instructions. The large difference found provides evidence for the efficacy of the sequential associations in auditory short-term memory. The difference in auditory recall under the 2 instruction conditions suggests that these sequential associations may, under certain conditions, be stronger than associations based on simultaneity.

The effect of the instruction conditions upon auditory recall becomes even more surprising when possible rehearsal strategies are considered. When the first 4 words were presented, S would probably attempt a quick rehearsal of all 4. Upon presentation of the second set, S would also rehearse those. If an ST probe is given, S only has to retrieve the word he had rehearsed either immediately before or after the probe. However, if S knows he is to get an SP prob[illegible] quandary. He cannot wait until al[illegible] items are presented and then attemp[illegible] rehearse the appropriate pairs, as h[illegible] will probably forget many items b[illegible] rehearses them. Also, the numbe[illegible] be shadowed appears quickly and d[illegible] allow much time for rehearsal. Th[illegible] strategy is to rehearse each se[illegible] it is presented and to then att[illegible] output to recode into the appropria[illegible] rs. Regardless of which strategy S [illegible], the SP condition should give su[illegible] call, as it does with the visual st[illegible] The fact that the SP condition is b[illegible] or auditory stimuli is evidence for th[illegible] ngth of the sequential associations.

Errors. The Ss were in[illegible] to report 1 word on every trial, a[illegible] give any word from the list if th[illegible] not know the correct word. The e[illegible] committed were classified into 4 categ[illegible] (a) same-place error—S responded [illegible] the word that had been presented i[illegible] same place as the probe when he should have given the word that occurred at the same time; (*b*) same-time error—S should have given the word that had occurred in the same place as the probe, but gave instead the word that had occurred at the same time; (*c*) same-modality error—S responded with a word in the correct modal[illegible] but which had been presented neither in the same place nor at the same time as the probe word; and (*d*) miscellaneous—omissions and all other errors. The proportion of each kind of error was tabulated, and the results are shown in Table 1. Proportions are reported rather than frequencies because of the different number of errors in the different conditions. When recall of auditory items was tested, there was a larger proportion of SP errors when an ST probe was given than of ST errors when an SP probe was given. The number of same-modality errors did not differ as a function of instructions. When a visual word was tested, there was a slightly greater proportion of ST errors. There was also a larger proportion of same-modality errors with the ST than with SP instructions.

The data on the types of errors made are consistent with the accuracy data in that they provide evidence for the hypothesized sequential associations in auditory short-term memory. If *S* knew he could not recall the correct word, one would expect him to report at random any word he could remember. Overall, the proportion of ST and SP errors should be approximately the same. The greater number of SP than ST errors and the high frequency of the same-modality errors suggest that it is somehow easier to retrieve an item connected to the probe by means of a forward or backward association than an item that occurred at the same time as the probe.

The occurrence of the sequential associations in auditory short-term memory cannot be regarded as resulting solely from a conscious decision on the part of *S* to process the stimuli in this way. In the present experiment, *S*s knew well in advance which type of probe they would get. They served in only 1 condition per day and had several practice trials before the experiment started. This should have enabled them to encode the stimuli appropriately. In spite of their foreknowledge of the probe condition and the rehearsal opportunities in this task, the SP probe was more effective for at least the first serial position. This suggests that in the time allowed to them, *S*s found it difficult to encode the 2 simultaneous auditory items as a pair, and the sequential associations predominated.

TABLE I

Proportion of Different Types of Errors in Experiment II

Type of error	Presentation modality: Auditory	Presentation modality: Visual
Same time instructions		
Same place	.304	.281
Same modality	.467	.302
Miscellaneous	.229	.417
Same place instructions		
Same time	.235	.340
Same modality	.451	.262
Miscellaneous	.314	.398

Discussion

The results of the present experiments, which used a bisensory–dichotic presentation, extend the findings of earlier studies that employed either the bisensory or dichotic presentation alone or a visual presentation of 2 simultaneous items. The *S*s clearly preferred to recall simultaneous or successive auditory and visual stimuli separately by modality. Two simultaneous visual stimuli are recalled as a pair, but sequences of dichotic auditory stimuli are recalled as 2 sequences, not in pairs. The sequential recall of dichotic stimuli occurs even when visual stimuli intervene between successive auditory stimuli. When a probe technique is used, the SP condition, which tested memory of a forward or backward association, was found to give higher recall for auditory than for visual presentation. For the ST condition, the difference between auditory and visual presentation was smaller and in the reverse direction.

The results of the 2 experiments reported also have implications for a theory of auditory and visual short-term memory. Recently, a number of investigators have hypothesized the existence of 2 separate short-term memory stores, one for auditory items and another containing information in verbal format (e.g., Crowder & Morton, 1969). An alternative form of the hypothesis is that the 2 stores are modality specific, one containing information about auditory items and the other containing visual information (e.g., Murdock & Walker, 1969).

The present data do not support one of these alternative hypotheses over the other. They do, however, suggest an explanation of one of the more puzzling findings in the area of auditory–visual differences. In a serial-probe experiment with lists containing both auditory and visual items, Murdock (1967) found that the best performance was obtained when both the probe and the TBR word were auditory. When either or both were visual, recall was considerably lower. The results of the present experiments indicate that successive auditory stimuli are rather strongly associated, and that this occurs whether or not *S* tries to encode in this

manner. When either or both of the probe and TBR word are visual, this strong association is absent and recall is lower. Thus, the hypothesis of sequential associations between successive auditory stimuli, in addition to accounting for the dichotic and bisensory split-span data, would appear to be useful in integrating within a unified theoretical framework the results of experiments on auditory and visual presentation in short-term memory and those on selective attention.

ASSOCIATION, DIRECTIONALITY, AND STIMULUS ENCODING[1]

ROBERT E. WARREN[2]

Columbia University

The degree of interference with color naming produced by the word used as a carrier for the color in a discrete-trial Stroop task was found to increase if an associatively related word was concurrently held in memory. The degree of interference varied directly with the associative strength of the connection between the memory word and the color word. A second experiment using unidirectional associates showed that interference with color naming increased only if the word being held in memory elicited the color word and not vice versa. It is suggested that the results support the hypothesis that activation of the memory representations of a word's associates is part of its encoding process.

Attempts to determine the structure of memory have recently centered on the process of stimulus encoding. Encoding as a general term includes all those transformations performed on the nominal stimulus before it assumes its final representation in memory. These transformations may theoretically include both additions to and loss of stimulus information. Encoding is of interest to the memory theorist because of its presumed relation to the structural properties of memory. It has been argued (Wickens, 1970) that the transformations employed in encoding are a function of the structural characteristics of memory. Thus, if one could specify what factors are involved in the initial encoding of words, this information would allow the inference of verbal memory structure.

Various models of memory have suggested different conceptions of the encoding process. Bower (1967) has proposed that encoding involves the specification of values along semantic dimensions and that words are represented in memory as groups of these values. Similarly, Conrad (1967) and others (e.g., Yntema & Trask, 1963) have suggested that encoding involves the amalgamation of particular components or the tagging of a central word unit to indicate specific characteristics. Operationally, however, the nature of encoding has often been assessed in terms of *S*'s reaction to some characteristic of "words as wholes." The proactive interference paradigm used by Wickens (1970), for example, appears to rely on binary decisions regarding the list membership of individual items (Loess & Waugh, 1967). Similarly, false recognition studies (Underwood, 1965) utilize the identification of individual words as old or new as an indication of previous encoding patterns.

The use of whole-word measures is often based on the theoretical position that specification of a particular component or dimensional value affects the representations in memory of not only the presented stimulus, but also of those words sharing the characteristic in question. In the false recognition paradigm, for example, presentation of the word ICE is said to produce implicit activation of words sharing a commonsense impression such as COLD (Kimble, 1968). This position suggests that one way to map out the extent and degree of encoding is to present a word and then test the activation of other words which bear some nominal relation to the presented item. If the words are found to be activated, the common nominal relation could be assumed to be part of the encoding process.

Changes in performance on a number of tasks as a function of word activation

can be predicted from a system of word recognition units or logogens proposed by Morton (1970). The logogen system as a whole combines sensory, contextual, and semantic information to identify which word has been encountered in any given situation. The system relies on an initial analysis of sensory information into components which are then routed to logogens which have been activated by similar information in the past. One logogen is assumed to exist for each word in a person's vocabulary, and each is composed of the following 3 elements: (*a*) a counter that increases in value each time stimulus information that corresponds to the word the logogen represents is encountered, (*b*) a motor program that represents the verbal production of the word, and (*c*) a threshold value that is fixed by the past frequency of occurrence of the word. Upon presentation of a word, counter values at logogens which correspond in whole or part to the physical representation of the word begin to increase as components are identified by the sensory analysis system. Counters at those logogens which correspond best to the actual word given increase in value at the greatest rate. When one of the logogens' counter values exceeds its threshold, its motor program is said to become available and is loaded into a response buffer by a central processing unit where it is held for output. Only one program can pass to the buffer at a time, so that if one program becomes available before another, the second will be delayed until the buffer is cleared.

Presentation of a word, then, produces what might be termed primary activation of a logogen. Besides reacting to sensory input, logogens can theoretically also be activated indirectly, as suggested earlier, when words sharing some common semantic feature or other relation are presented. This secondary activation is produced by what Morton (1970) termed the cognitive system. Secondary activation produces counter increments at related logogens, but these increments are thought to be of lesser magnitude and to begin longer after word presentation than those produced by primary activation at th[illegible]n for the word actually encounter[illegible]

In the present experin[illegible]erference with color naming in a di[illegible]l Stroop (1938) task was used to in[illegible]he degree of activation of the wo[illegible] tested In the Stroop task, *S* is [illegible] to name the color of ink in which a[illegible]s printed while attempting to ignor[illegible]em itself In the traditional Stroop [illegible] the base items printed in colors ar[illegible] of Xs or antagonistic color words [illegible] is, the word RED would appear i[illegible]ink, the word YELLOW in red ink, a[illegible]on. The typical finding is that it [illegible]s longer to name the colors when [illegible]se items are antagonistic color nam[illegible] when they are rows of Xs (Jense[illegible] Rohwer, 1966). In an extension of S[illegible]'s work, Klein (1964) has shown tha[illegible] naming latency is also increased ove[illegible] Xs control if common words unrel[illegible] to color are used as base items in the [illegible]

For the logogen system, in[illegible]erence in the Stroop situation occurs because stimulus information activating 2 logogens is present, i.e., those of the base item and the ink color name. If the motor program for the base item becomes availabl[illegible]efore the program for the ink color name, [illegible] production of the color name will be delayed because of the response-buffer space limitations mentioned earlier. The greater the level of activation of the logogen for the base word prior to stimulus presentation, the more likely it is that this will occur. This means that any operation that increases the base word's level of activation prior to its presentation will produce an increase in color-naming latency. It follows that if secondary activation occurs during the encoding of a word, the degree and pattern of activation can be assessed by presenting other words as base items in a Stroop task subsequent to presentation of the word in question and observing whether or not color-naming delays are produced.

Previous work using this technique (Warren, 1972) has shown that the name of the taxonomic category from which a triad of words is drawn, as well as any of the words themselves, produces an in-

crease in color-naming latency when used as the base word in a Stroop task given subsequent to the presentation of the triad. Experiment I tested whether words which appear as responses in association norms produce similar increases in color-naming latencies when used as color base words after their associative stimuli have been encountered by *S*.

To review the argument presented so far, color-naming latency in the Stroop task is thought to vary with the degree of activation of the logogen of the word used as a carrier for the color. If the level of activation of Word B's logogen is somehow increased during the presentation of Word A, the degree of interference with color naming produced when Word B is used as a base item in a subsequent Stroop task should also increase. Experiment I tested whether such an increase in activation occurs when Word A and Word B are related associatively. That is, the following 2 questions are posed: (*a*) Does the associative relationship indicated by standard association norms parallel an underlying pattern of activation in the logogen system such that when a stimulus, Word A, is encountered the logogen of its primary response, Word B, is activated? (*b*) Does the frequency of a response, Word B, to a stimulus, Word A, in an association test reflect the degree or probability of activation of the logogen for Word B when Word A is given?

Experiment I

Method

Subjects. Five male and 5 female students at the University of Oregon were run individually for a single 45-min. session. They were paid $1.50 for their participation.

Procedure. The *S*s were seated at a 2-channel tachistoscope used to present the visual stimuli in the experiment. Prerecorded auditory stimuli were presented to *S*s over earphones.

Each trial in the experiment consisted of 3 phases. In order of occurrence, these were (*a*) auditory word presentation, (*b*) visual word presentation and color naming, and (*c*) recall of the auditory word. In the first phase, the word READY was presented over the earphones followed by a prerecorded auditory word.

Immediately after the presentation of the auditory word, a word printed in colored ink and centered on a white field was shown in the tachistoscope. The word remained visible until *S* had named aloud the color of ink in which it was printed. Naming the color activated a voice-operated relay which terminated the visual display and stopped a Hunter millisecond clock that had been started at the onset of the visual word. The *S*s were instructed to name the color of ink in which a word was printed as rapidly as possible and to ignore the word itself.

In the final phase, which followed color naming directly, *S* recalled aloud the word given auditorily in the first phase.

Both color-naming latency in milliseconds from the onset of the visual item and recall accuracy were recorded. There was a 15-sec. interval between trial onsets.

Design and materials. Thirty pairs of associated words were selected from Palermo and Jenkins (1964). The word pairs and their associative strengths appear in Table 1. Three groups of 10 pairs each were formed with mean associative strengths of .630 (high associative strength), .334 (medium associative strength), and .152 (low associative strength). Associative pairs were chosen so that the range and average frequency of occurrence in English (Kučera & Francis, 1967) of the response members of the 3 groups were approximately equal.

During the experiment, the logogen activation of the response words was tested by presenting them in the color-naming phase of a trial. Interference with color naming produced by each response word was assessed under 2 conditions: (*a*) after the stimulus to which it was a primary associative response had been given auditorily (test condition) and (*b*) after auditory presentation of an unrelated word (control condition). For example, the response word GIRL was preceded in the test condition by the auditory word BOY, while in the control condition it was preceded by the auditory word CASE. The unrelated words used as auditory stimuli in the control condition are shown in Table 1 matched with the assigned response word.

The experiment thus consisted of 6 conditions, resulting from test and control assessment of the color-naming interference produced by each of the response words in the high, medium, and low associative strength groups.

Auditory stimuli in the experiment were prerecorded and presented over earphones. Words presented visually were printed in colored ink in lowercase letters and subtended an average visual angle of less than 3°. The 5 colors of ink used were red, blue, yellow, green, and purple. Five decks of stimulus cards were made up. In each deck, one-fifth of the responses in each associative strength group was printed in each color. Across the 5 decks, each response word appeared in each color. Within a single deck, a response word was

presented in the same color on both its test and control condition appearances. Each deck was used with one-fifth of the *Ss*.

Trials were ordered and presented in 2 35-trial blocks, Blocks A and B, with a 2-min. break between blocks. Each block began with 5 filler trials followed by 30 experimental trials. Within each consecutive set of 6 experimental trials, 1 trial representing each condition was given. Colors were assigned so that no color was repeated on consecutive trials.

All of the response words were shown in each block. Half of the response words in each associative strength group were presented in the test condition and half in the cont[illegible] in Block A. The words were then [illegible]nged and presented in the opposite conditio[illegible] Block B. Half of the *Ss* received Block A [illegible] and half, Block B first. Prior to the begin[illegible] of the experimental trials, *Ss* were show[illegible]mples of each of the 5 colors being used i[illegible] of rows of 5 lowercase Xs printed in colo[illegible]

Results

Recall of the auditory wor[illegible]as good with only 1.5% of the possi[illegible] memory errors occurring (9 out of 60[illegible]ossible). All but 1 of these errors see[illegible] to be acoustic in nature, e.g., recall o[illegible]EAD for THREAD. The 1 remaining err[illegible]was the intrusion of the color word sh[illegible] on the same trial. Because correct [illegible]al perception of the auditory word c[illegible] not be assumed for trials on which m[illegible] errors occurred, these trials were ex[illegible] from further analysis.

Color-naming accuracy was [illegible] good with errors occurring on only 1[illegible] of the trials given (8 out of 600). Co[illegible]naming errors consisted of calling out [illegible] wrong color name (4 8), or prematurel[illegible]ripping the voice key with a hesitation [illegible]nd such as "ah" or "er" (4 8). These t[illegible]ls were also discarded.

Mean color-naming latencies in milliseconds for each of the 6 experimental conditions were determined for each *S*. Overall means are shown in Table 2. A repeated measures analysis of variance was performed on the data with *Ss*, condition (test, control), and associative strength (high, medium, and low) as factors. The analysis showed a significant main effect for condition, $F(1, 9) = 15.44$, $p < .005$, and a significant Condition $\times$ Associative Strength interaction, $F(2, 18) = 6.13$, $p < .01$. The main effect for associative strength did not approach significance, $F(2, 18) = 2.30$, $p > .05$.

Winer's (1962) method for a priori comparisons of treatment totals showed latencies in the high–test condition to be greater than in the high–control condition ($p < .001$). Similarly, medium–test latencies were greater than medium–control latencies ($p < .025$). Latencies in the low–test

TABLE 2

Mean Color-Naming Latencies (in msec.): Experiment 1

Condition	Associative strength group		
	High	Medium	Low
Test	929	906	858
Control	834	856	838

and low–control conditions did not differ significantly ($p > .05$).

In addition to the analysis of variance on within-*S*s means, mean color-naming latencies across *S*s for each stimulus–response pair were determined for both test and control conditions. The ratio of the test to the control mean was then determined for each pair and the correlation between these values and the corresponding associative strengths of the word pairs was calculated. A positive correlation was found, $r = .41$, $p < .05$.

The measure of associative relation used to form the associative strength groups in the experiment was that of forward associative strength, i.e., the frequency with which the auditory word elicted the color word as a response. Backward associative strength was not controlled for, and examination of bidirectional association norms (Keppel & Strand, 1970) shows that a positive correlation existed between the forward and backward associative strengths of the pairs used, $r = .36$, $p < .05$. To examine the influence of this backward associative relation on color-naming latencies, a partial correlation analysis was done on the test–control ratios and the 2 sets of association values for the word pairs in the experiment. The analysis showed the partial correlation of the interference ratios with forward associative strength to be significant, $r = .36$, $p < .05$, while that with backward associative strength was not, $r = .12$, $p > .05$.

Discussion

The findings of Experiment I appear to confirm that secondary activation of words given frequently as responses in association tests does occur during the encoding of the appropriate stimulus word. The degree or probability of activation seems to follow quite closely the frequency with which the word is given as a response. The greater the response frequency, the larger the interference with color naming produced in the test condition.

The word pairs in Experiment I were chosen without regard to the type of associative relation between the words. That is, associations between synonyms (SPEAK–TALK), antonyms (SMOOTH–ROUGH), and words joined by contiguity or function (BED–SLEEP) were all included. It is probably the case that these different associative types reflect different patterns of activation. Differences of this sort have been found in several studies of false recognition (e.g., Grossman & Eagle, 1970). It should also be noted that for all of the pairs of associates used, only primary responses were selected. There is some indication from other studies (e.g., Cramer, 1969) that nonprimary responses do not function in the same manner as primaries.

It has been assumed that it is secondary activation taking place during the presentation of the auditory word in Experiment I that is producing the subsequent interference in the color-naming phase. Since the secondary activation produced by the color word does not become effective until sometime after its presentation, any activation of the recall-word logogen is delayed and unlikely to interfere with color naming. This view is supported by the partial correlation results. Because of the critical nature of the assumption, however, a second experiment which tested it directly was carried out. In Experiment II, word pairs with strong unidirectional associative relations (A→B but B↛A) were selected and the pair member which strongly elicited its mate was assigned to either the recall-word or color-word role in trials similar to those used in Experiment I.

Experiment II

Method

Subjects. Twelve male and 12 female *S*s recruited from the staff and undergraduate populations of Columbia University were run individually for a single ½-hr. session. They were paid $1.75 for their participation.

Procedure. The *S*s were seated in front of a rear projection screen on which all the stimuli in the experiment were shown. A Gerbrands 2-channel projection tachistoscope was used to present the stimulus material.

Each trial in the experiment consisted of 3 phases. In order of occurrence, these were (*a*) recall-word presentation, (*b*) color-word presentation and color naming, and (*c*) recall of the word shown in the first phase.

The word given for later recall was printed in white capital letters on a black background and shown for 800 msec. This exposure was followed by a dark field which lasted 1,000 msec. At the end of this interval, a word printed in colored lowercase letters on a black background was shown and remained visible until *S* had named aloud the

color in which it appeared. Naming the color activated a voice operated relay which terminated the visual display and stopped a Gerbands millisecond clock that had been started at the onset of the colored word. The *S*s were instructed to name the color as quickly as possible and to ignore the word itself. After naming the color, *S* recalled aloud the word shown in white during the first phase of the trial.

Color-naming latency in milliseconds from the onset of the colored word and recall accuracy were recorded. There was a 10-sec. interval between trial onsets.

Design and materials. Two sets of 12 associatively related word pairs were chosen from the bidirectional association norms collected by Keppel and Strand (1970). In both groups, one member of the pair elicited the other as a response, while the opposite relation was weak or nonexistent. For one of these groups (forward association group), the pair member which elicited its mate was assigned to be a recall word during the experimental trials while the other member of the pair was assigned to appear as a color word. For the other group (backward association group), the words were assigned to opposite roles. For the forward association group, the average associative strength for the recall-word–color-word relation was .397 and for the color-word–recall-word relation, .020. For the backward association group, these same values were .021 and .404, respectively. The sets of word pairs are shown in Table 3, along with the individual pair associative strengths. The range and average frequency of occurrence in English (Kučera & Francis, 1967) of the pair members assigned to the color-word role in the 2 groups were approximately equal.

The logogen activation of the color words tested by measuring color-naming latency Experiment I. Color-naming latency for word was determined under the following 2 co tions: (*a*) after presentation of the other men of the associative pair as the word to be rec in the first phase of a trial (test condition) (*b*) after presentation of an unrelated word Phase 1 (control condition). For exampl word STAR from the forward association grou tested after its associate MOON in the test condi and after CHAIR in the control condition. Simil LOUD, from the backward association grou tested after SOFT in the test condition and SKY in the control condition. The unrelated presented as recall words in the control con are shown in Table 3 matched with the appro associative pair.

The experiment, then, consisted of 4 condit resulting from assessment of the color-naming l cies produced by the color words from the forv and backward association groups under test control conditions.

Recall words presented in the first phase trial and the colored words presented in the se phase subtended average visual angles of 2 The 4 colors used for the color words were purple, yellow, and green. Four decks of color- slides were prepared. In each deck, one-fourth the words in each experimental condition appe in each color. Across the 4 decks, each word peared in each color. Within a single deck, a w was presented in the same color on both its test control appearances. Each deck was used for o fourth of the *S*s.

Trials were ordered and presented in 2 28-trial blocks, Blocks A and B, with a 1-min. break between blocks. Each block began with 4 filler trials followed by 24 experimental trials. Within each consecutive set of 4 trials, 1 trial from each condition was given. Colors were assigned so that no color was repeated on consecutive trials.

All of the color words were shown in each block Half of the color words in the forward and backward groups were presented in the test condition and half in the control condition in Block A. The words were presented in the opposite condition in Block B. Half of the *S*s received Block A first and half, Block B first. Prior to the beginning of the first block, *S*s were shown 2 examples of each of the 4 colors being used. Colors were presented in the form of rows of 5 lowercase Xs printed on a black background.

Results

Retention of the recall words was quite good, with only 1.0% of the possible memory errors occurring (11 out of 1,152). The following 4 types of memory errors were noted: (*a*) omissions (4/11), (*b*) intrusion of the color word from the same

TABLE 4

Mean Color-Naming Latencies (in msec.): Experiment II

Condition	Associative direction group	
	Forward	Backward
Test	964	930
Control	892	930

trial (4/11), (*c*) intrusion of a recall word from a previous trial (2/11), and (*d*) intrusion of a color word from a previous trial (1/11). No particular pattern of errors was noted across the 4 conditions. Since correct initial perception of the recall word could not be assumed for trials on which memory errors occurred, these trials were discarded and not used in subsequent analyses.

Color-naming accuracy was also good with errors occurring on 1.7% of the trials given (20 out of 1,152). The following 6 types of color-naming errors were noted: (*a*) naming the wrong color (14/20), (*b*) naming the color word itself (2/20), (*c*) prematurely tripping the voice key with a hesitation sound such as "uh" or "er" (1/20), (*d*) naming the color correctly but too quietly to trip the voice key (1/20), (*e*) calling out the recall word for that trial (1/20), and (*f*) producing no response before the onset of the next trial (1/20). The 2 Type *b* errors occurred on trials in the forward–test condition; the single Type *e* error occurred in the backward–test condition. Trials on which color-naming errors occurred were also discarded.

Mean color-naming latencies in milliseconds for each of the 4 conditions were determined for each *S*. Overall means are shown in Table 4. A repeated measures analysis of variance was done on the data with subjects, condition (test, control), and associative direction (forward, backward) as factors. The analysis showed a significant main effect for condition, F (1, 23) = 8.48, $p < .01$, and a significant Condition × Associative Direction interaction, F (1, 23) = 5.66, $p < .05$. The main effect for associative direction was not significant, F (1, 23) < 1.0, $p > .05$.

Winer's (1962) method for a priori comparisons of treatment totals showed latencies in the forward–test condition to be greater than in the forward–control condition ($p < .001$). The comparison of backward–test and backward–control totals showed no significant difference ($p > .05$).

Discussion

The results of Experiment II appear to support the notion that the color-naming interference that occurs in this paradigm is due to activation of the color base word during the encoding of the recall word. The alternative hypothesis, that the encoding of the color word activates the recall word which then interferes with color naming, does not seem to be supported. Both the presence of the forward–test and forward–control latency difference and the absence of any difference between the backward–test and backward–control latencies contribute to this conclusion.

The lack of any interference in the backward associative conditions does not mean that the logogen for the recall word is not activated after color-word presentation. Rather, it indicates that the time course of activation is such that the color name becomes available and is loaded into the response buffer before the logogen for the recall word passes its availability threshold. Interference in the color-naming task can occur only when a motor program other than that for the color name is loaded in the buffer first. This indicates, as suggested earlier, that secondary or semantic activation does not match in degree or latency the activation caused by sensory input.

Several questions remain to be explored in future research. It is likely that the different types of relations obtained in an association test result from quite different underlying semantic processes. The patterns of activation which parallel these processes may vary both in extent and what might be termed rise time or latency. Experimental variation of semantic relation and of the interval between word presentation and the test for activation may help tease out these encoding patterns. The problem of whether the secondary activation function is set into motion by any amount of logogen activation or whether it only takes place once a logogen passes threshold is also unanswered. There are some indications from other paradigms (e.g., Lewis,

1970) that this latter step may indeed not be necessary.

SHORT REPORTS

PRONOUNCEABILITY AS AN EXPLANATION OF THE DIFFERENCE BETWEEN WORD AND NONSENSE ANAGRAMS[1]

RICHARD S. FINK AND ROGER L. DOMINOWSKI[2]

University of Illinois at Chicago Circle

The present study involved a test of the hypothesis that differences in pronounceability can account for the finding that word anagrams are more difficult to solve than nonsense anagrams. The results, based on 48 anagrams of each type, indicated that word anagrams were more difficult when pronounceability was ignored but that the difference between anagram types was eliminated when pronounceability was statistically controlled. In addition, pronounceability was strongly related to problem difficulty within each anagram class. It was concluded that assessing the ease with which an anagram can be verbally encoded eliminates the need to determine if it has meaning.

An anagram problem involves presenting *S* with a letter sequence and asking him to discover the word which can be made by rearranging the letters. The anagram presented is typically a nonsense string (e.g., given SLACH, find CLASH) but can itself be a word (e.g., given SAUCE, find CAUSE). Previous research has demonstrated that word anagrams are more difficult to solve and that the difference between word and nonsense anagrams can neither be explained in terms of differences in the frequencies of the bigrams constituting the anagrams nor be dismissed as a consequence of methodological biases (Ekstrand & Dominowski, 1968).

In attempting to explain the difference between word and nonsense anagrams, the most obvious approach is to consider the fact that, by definition, word anagrams have denotative meaning and nonsense anagrams do not. However, an alternative, more general, explanation has been proposed. Two studies using only nonsense anagrams have demonstrated that the easier an anagram is to pronounce, the harder it is to solve (Dominowski, 1969; Hebert & Rogers, 1966). The proposal is that, on the average, word anagrams will be easier to pronounce than nonsense anagrams and will be more difficult to solve for that reason. The present study provided a test of this hypothesis.

In order to use a large number of problems, no attempt was made to strictly equate word and nonsense anagrams in terms of pronounceability. The rationale was that, in order to test the hypothesis, all that was needed was reasonably wide variation in pronounceability both among word anagrams and among nonsense anagrams, and overlapping distributions. If the difference between word and nonsense anagrams is to be explained in terms of pronounceability, then it must be true not only that the difference between word and nonsense anagrams is eliminated when pronounceability is (statistically) controlled but also that pronounceability affects problem difficulty within each anagram class.

Method. Using the Olson and Schwartz (1967) tables, 48 word anagrams and 48 nonsense anagrams were constructed. The solutions to the nonsense anagrams were chosen to be similar in language frequency to the solutions of the word anagrams. By using the letter orders of the word anagrams to construct the nonsense anagrams, the number of letter moves required to reach solution (Dominowski, 1966) was equated for the 2 types of anagrams. For each of the 96 anagrams, the mean bigram frequency was calculated, using the Mayzner and Tresselt (1965) norms.

For each problem, 3 additional measures were obtained, using a total of 103 *Ss* all of whom were introductory psychology students fulfilling a course requirement. To allow a check on the comparability of the solutions to the 2 types of problems, the 96 solutions were presented, in random order, to 28 *Ss* who were asked to judge how often each word appears in print, using a magnitude estimation procedure devised by Underwood (1966).

To measure anagram pronounceability, the 96 anagrams were presented one at a time to each of 23 *Ss*, with *S* instructed to pronounce each item as though it were an English word. It was pointed out that some of the items would be common words and some would not, but that *S* was to pronounce every item as though it were a word. Tape recordings of *S*'s responses were made, and the tapes were subsequently run through a Grason-Stadler Model E7300A-1 voice operated relay which triggered Hunter Model A Series D Klockounters. The time taken for each pronunciation was measured in milliseconds.

Problem difficulty was determined by presenting the 96 anagrams to 52 *Ss*, run in 3 small groups. The *Ss* were told what an anagram is, shown examples of word and nonsense anagrams, and told that for each problem their task was to find the word which could be made by rearranging the 5 letters presented. The 96 problems were presented

[1] This article was completed while R. L. Dominowski was a research fellow at the University of Aberdeen, Scotland. The authors are grateful to Sheldon Rosenberg for his help in the measurement of pronunciation times.

on a screen in random order. For each problem *Ss* were given 30 sec. to solve and were instructed to mark an X in the answer space if they had not solved a problem at the end of the 30-sec. period.

Results and discussion. The analyses utilized problems ($N = 96$) as the replicate. For each problem, the following measures were available: number of solutions (possible range 0–52), type of anagram (word vs. nonsense), anagram pronunciation time, judged familiarity of the solution, and anagram bigram frequency. Using number of solutions as the criterion, a multiple-regression equation was determined with the other 4 variables serving as predictors. In this analysis, significant contributions were made by only 2 predictors, anagram pronunciation time, $\beta = .64$, $p < .001$, and solution familiarity, $\beta = .16$, $p < .05$. These 2 results confirm previous findings that anagrams that are more difficult to pronounce (= have longer pronunciation times) or that have more familiar solutions are easier to solve (e.g., Dominowski, 1967, 1969; Hebert & Rogers, 1966). Anagram bigram frequency did not independently contribute to the prediction of problem difficulty, a finding consistent with the pattern of earlier results indicating that this variable reflects at best a minor characteristic of anagrams (e.g., Dominowski, 1967).

The distribution of familiarity judgments for word anagrams ($M = 68.6$, $SD = 26.6$) was nearly identical to that for nonsense anagrams ($M = 62.6$, $SD = 25.5$); thus the effect of solution familiarity need not be considered in examining the difference between anagram types. However, as expected, word anagrams ($M = .208$ sec.) were easier to pronounce than nonsense anagrams ($M = .273$ sec.). The results presented above indicate that pronounceability is more important than anagram type (word vs. nonsense) in accounting for anagram difficulty. The following analysis demonstrated this more directly.

If pronounceability was ignored, the mean number of solutions for word anagrams (12.0) was significantly lower than that for nonsense anagrams (16.6), $F(1, 94) = 4.85$, $p < .05$. If, however, pronounceability was used as a covariate, the mean difference was reduced to near zero ($F < 1$). Furthermore, pronounceability was strongly related to problem difficulty both within the class of word anagrams ($r = .61$) and within the class of nonsense anagrams ($r = .62$). These results indicate that pronounceability meets the criteria of a satisfactory explanation of the difference between word and nonsense anagrams. For each type of anagram considered separately, the longer it takes to pronounce an anagram, the easier the anagram is to solve, and the difference in difficulty between word and nonsense anagrams is eliminated when their difference in pronounceability is taken into account.

The results support the conclusion that word anagrams can be considered simply as a set of anagrams which are on the average relatively easy to pronounce. Stated differently, the findin[illegible] gest that there is no need to separate ana[illegible]ms which happen to be words from other anagr[illegible]s of equivalent pronounceability. Although the [illegible]ent results do not support the notion that wor[illegible]nagrams are harder to solve because they hav[illegible]aning, the emphasis on pronounceability is co[illegible]tent with the more general proposal that the mo[illegible]rganized or cohesive an anagram is, the mor[illegible] it will be to solve.

The pronounceability of an anagram [illegible] the extent to which it conforms to the str[illegible] of the language. For 5-letter anag[illegible] sible range is from a string which m[illegible] be considered as 5 units to an anagr[illegible] easily be encoded as a single unit (a [illegible] The accumulated evidence on anagram solv[illegible] that *Ss* first try to think of words based [illegible] rearrangement of the anagram, attemp[illegible] duce syllables when the first meth[illegible] (e.g., Kaplan & Carvellas, 1968). Pres[illegible] [illegible]sily pronounced anagram provides *S* with [illegible] [illegible]perly structured but incorrectly orde[illegible] It is likely that, given such an anagr[illegible] will [illegible]ntain its plausible but incorrect or[illegible] to find the solution. In contrast, [illegible]orly structured anagram (e.g., a string [illegible]ants followed by a vowel), *S* is unlikel[illegible] its order but will rather quickly rearra[illegible]ted letters into a plausible basis for a word [illegible] also possible that *S* will simply perseverate o[illegible] pronounced anagram; i.e., solution att[illegible] will be made at a slower rate, at least initially. [illegible]hough it seems unlikely that this mechanism alo[illegible] is responsible for the effect of pronounceability. [illegible] the appropriate record were obtained, it would b[illegible] possible to determine if anagram pronounceability affects both the rate and the nature of solution attempts.

WHEN IS RECALL SPECTACULARLY HIGHER THAN RECOGNITION? [1]

MICHAEL J. WATKINS [2]

Yale University

Tulving has described a paired-associate procedure in which the B terms were recalled better than they were recognized. The present experiment replicated and magnified this finding. It is considered that these results argue against current models in which recall and recognition are characterized as qualitatively distinct processes

There is currently some disagreement about whether recall and recognition are to be accounted for by the same or by different mechanisms. The predominant view postulates 2 qualitatively distinct processes (Kintsch, 1970; Underwood, 1972). According to this theory, recall involves a search-cum-implicit-retrieval stage, followed by a decision stage, in which the retrieved information is either accepted as appropriate or rejected. In recognition, the retrieval of an available item is inevitable (or "automatic"), and hence only the decision phase is functionally operative. Other students of memory reject the notion that retrieval is bypassed in recognition. Thus, Tulving and Thomson (1971) argue that while retrieval is usually comparatively more successful in recognition, the retrieval phase is nonetheless a distinct and fallible component of the recognition process, just as it is in recall.

One implication of the dual-process theory is that recognition should be higher than recall. The only exception is when there is no retrieval failure in recall, in which case the 2 measures should be identical. In a paper entitled "When is recall higher than recognition?" Tulving (1968) reported an experiment in which *S*s learned a paired-associate list to a criterion of 2 successive error-free trials, and were then given a recognition test of the B terms. Approximately 10% of the B terms were not recognized. Tulving's results are clearly difficult to interpret in terms of the dual-process theory. That the recall advantage was obtained with a paired-associate procedure rather than with free recall does not detract from its theoretical importance. To be recalled, an item must be represented or "available" in memory, and an automatic-access theory of recognition predicts recognition of *all* available items. However, Tulving's recall superiority was rather small and it might be held that the experiment was not totally conclusive, in that (*a*) incorrect identification was less frequent than failure to identify a presented item, and hence the recall advantage would have been even less if *S*s were forced to make more recognition responses; and (*b*) a few items may have become unavailable during the course of the recognition test, perhaps as a result of considering the distractor items.

In the demonstration to be reported, the procedure was free from these potential sources of artifact, and yet yielded a greatly magnified recall advantage.

Method. Twenty male and female undergraduate psychology students were tested individually or in small groups. In outline, all *S*s were presented with and tested on a practice paired-associate list, and were then shown an experimental list of which certain pairs had been designated critical. Immediate testing was confined to noncritical pairs. After a filled interval all *S*s were given free and forced choice recognition tests of the critical B terms. Finally the critical A terms were presented in a conventional cued recall test of the corresponding B terms.

For both the practice and experimental lists, the A terms contained 5 letters and the B terms 2 letters. The majority of both the A and B terms were "nonsense words," insofar as they do not appear in the dictionary. However, if each B term was added to its A term, a common word was formed. This was true for all pairs of both practice and experimental lists. Neither A nor B terms were repeated within or between lists. There were 20 pairs in the practice list, while the experimental list contained 39 pairs of which 24 were designated critical and 15 noncritical. The *S*s were randomly assigned to 2 groups of 10. Both groups saw the same practice list but different forms of the experimental list. The 2 variants of the experimental list differed only in the B terms of the critical pairs. Examples of critical pairs presented to one group of *S*s are SPANI - EL, EXPLO - RE, LIQUE - FY, HIDEO - US and AMNES - IC; the corresponding pairs for the other group would be SPANI - SH, EXPLO - DE, LIQUE - UR, HIDEO - UT, and AMNES - TY. The *S*s were not explicitly informed of the nature of the relationship between A and B terms, although this was presumably perfectly obvious from the first 1 or 2 pairs of the practice list. The order of the A terms for both critical and noncritical pairs was identical for the 2 groups of *S*s; the first and last 5 pairs were noncritical, while the remaining 5 noncritical pairs were randomly allocated among the 24 critical pairs.

Presentation was by means of a closed-circuit television system, with successive pairs typed in uppercase, the A term on the left, the B term on the right, and a hyphen between the 2 terms. The pairs were presented at a 4-sec. rate.

Immediately following the presentation of the practice list, *S*s were given a list of all 20 A terms,

in a new random order. The *Ss* wrote down, at their own rate, as many of the B terms as they could recall.

The experimental list was simply announced as "next list" and the *Ss* were led to believe that they would be tested in just the same way as for the practice list. In fact at this stage they were merely given a recognition test of the 15 noncritical pairs. The test consisted of the presentation of the 15 noncritical pairs plus 15 new pairs of the same type. The *Ss*' task was to circle 15 pairs which they thought most likely to have appeared in the preceding list. The purpose of this test was simply to reduce the probability of covert retrieval and rehearsal of critical pairs, and the impression was given that this test terminated the experiment.

The *Ss* next participated for 30–40 min. in a separate experiment, which involved the free recall of a series of word lists. Following this experiment, each *S* was unexpectedly given a list containing the 24 critical B terms seen in the experimental list, randomly mixed with the 24 critical B terms which had been presented to the other group of *Ss*. Instructions were first given for a free recognition test; *Ss* were to check any item recognized as occurring in the second list. The *Ss* were then given a different pen and asked to check further items which they thought most likely to have been presented before, until a total of 24 had been checked in this forced recognition test. Finally the *Ss* were given a cued recall test of the 24 critical pairs. The 24 A terms were presented in random order, and *Ss* were instructed to write down the B terms with which they had been paired. Thus for both groups of *Ss* the recognition and cued recall tests were identical, although the correct responses differed. In both tests *Ss* were given as much time as they needed.

The confounding of type of test and order of test may have given a small advantage in favor of the recognition test. However, this effect is not critical in that it would merely serve to reduce the predicted recall advantage. The converse possibility that exposure to the recognition items may have enhanced recall seems unlikely, in that the recall targets and the recall lures were equally exposed in the recognition test.

Results. Essentially identical patterns of results were obtained for the 2 groups of *Ss*. The 2 sets of data were therefore pooled. For all 20 *Ss* the number of presented critical B terms successfully recalled was greater than the number freely recognized, and equaled or exceeded the number responded to in the forced choice recognition test despite the fact that half of the items in the latter condition could have been identified by chance. Table 1 shows the mean probability of correct response for both presented and nonpresented (control) items in the recognition and recall tests. The control probabilities were used to estimate the amount of guessing in each of the test conditions. In detail, the difference between the presented and control probabilities for each test condition was divided by the probability of not responding to a control item. For example, the corrected free recognition probability was given by .14 − .07, divided by 1 − .07, that is, .08. These corrected probabilities are also shown in Table 1.

TABLE 1

PERFORMANCE AS A FUNCTION OF MEMORY TEST

Item	Free recognition	Forced recognition	Cued recall
Probability of correct response	.14	.52	.72
Probability of incorrect response	.07	.48	.14
Corrected probability of correct response	.08	.09	.67

Discussion. The results clearly support Tulving's (1968) conclusion that in some circumstances information may be recalled better than it can be recognized. Moreover, the present recall advantage was large. It is fun to speculate how the present paradigm might be refined to further accentuate this advantage—perhaps to perfect recall and zero (chance) recognition. Recall performance could presumably be increased by reducing the retention interval, or else by improving the original learning. One way of enhancing the initial learning of the A–B pairs would be to reduce the presentation rate, while a second would be to instruct the *Ss* to form a visual image comprising the A and B terms in interaction (Bower & Winzenz, 1970)—a strategy to which the present material would lend itself particularly well. Recognition performance could probably be reduced by further encouraging attention during presentation to be focused on the A–B pairs as such, and less on the individual terms. One way of achieving this would be to present to one group of *Ss* A–B pairs such as PLUN*ER - ****G**, REVEN*E - *****U*, etc. while the second group would see PLUN*ER - ****D**, REVEN*E - *****G*, etc. It is likely that the B terms would be readily retrieved on presentation of the A terms, yet poorly recognized.

Of course the technique being exploited with such a procedure, as in the experiment reported, involves making only the A–B *pairs* meaningful, thereby encouraging *Ss* to pay little attention to the individual A and B elements. It is conceded that such contrived procedures are not representative of those used in most verbal memory studies, and that the finding of recall that is better than recognition is likewise unusual. But the finding is not without theoretical significance, in that it poses a difficulty for the dual-process theory. According to this theory, failure to recognize an item indicates that it is not available in memory; however, in the present experiment the availability of a substantial proportion of nonrecognized items was demonstrated by their subsequent recall. Moreover, to interpret the obtained recall advantage in terms of the organization of nominal or *E*-defined units into very different functional units is of little comfort to the dual-process theorist, for "If retrieval and recognition processes can be separated as neatly as the dual process theory implies, organization of the

learning material can have no effect upon recognition, since organization facilitates retrieval and retrieval in recognition is trivial [Kintsch, 1970, p. 280]."

It might be thought that the present results simply demonstrate a tendency to encode material into whole words rather than partial ("nonsense") words. While this may be largely true for the present experiment, it is argued here that hierarchical structuring does not terminate at the level of the word; rather the general principle of organizing or chunking is emphasized. In fact, in the present experiment 20% of the B terms were words in their own right, yet were apparently not well encoded as separate elements. Moreover, in Tulving's (1968) experiment all the terms (both As and Bs) were meaningful words, yet at least some were encoded in a higher order unit.

One way of conceptualizing the present findings is to assume that an event is remembered only when a retrieval cue makes contact with the stored representation of the event. With paired-associate and recognition procedures, the retrieval cue is the perception of the A term and nominal "target," respectively. In free recall, the nature of the retrieval cue may not be obvious. In all cases, however, successful retrieval follows only when the retrieval cue matches the item trace, as originally encoded (Tulving & Watkins, in press). According to this view, when is recall higher than recognition? The answer is ". . . whenever retrieval cues present at the recall test are more effective in providing access to stored information than are retrieval cues present at the recognition test [Tulving, 1968, p. 54]." And when is recall spectacularly higher than recognition? Whenever the difference in effectiveness of the 2 cues is a spectacularly large one.

APPARENT SLOWING OF BIMANUALLY ALTERNATING PULSE TRAINS[1]

SEYMOUR AXELROD[2] AND MICHAEL NAKAO

Department of Psychiatry, State University of New York at Buffalo

Auditory clicks presented in rapid alternation to the 2 ears are heard as slower than clicks presented at the same rate to a single ear. We examined here a similar phenomenon in somesthesis. Thirty *S*s compared the rates of bimanually alternating taps with the rates of taps presented to a single hand, or vice versa. In terms of inter-*S* consistency, of the dependence of degree of perceptual slowing on repetition rate, and of the quantitative aspects of the dependence, the somesthetic results were similar to those obtained in an earlier auditory experiment, suggesting that the apparent slowing in the 2 modalities of stimuli alternating between receptive surfaces on the 2 sides of the body has a common basis central to modality-specific afferent structures.

When rapidly repeated clicks are presented alternately to the 2 ears, their apparent repetition rate is slower than that of clicks presented at the same objective rate to one ear alone (Axelrod, Guzy, & Diamond, 1968). Similarly, the numerosity of dichotically alternating stimuli is less accurately reported than that of monotic ones (Guzy & Axelrod, 1972; Holden, 1973).

These phenomena reveal a limitation in the processing of bilaterally alternating stimuli. If such limitation is unique to audition, then it would make sense to suppose that the underlying neural mechanisms are located in audition-specific structures, and that the limitation thus arises relatively early in the series of events from stimulus to perception. Explanations might then invoke the sort of contralaterally inhibitory process found, e.g., in single units of the cat's inferior colliculus (Erulkar, 1959). But if a similar limitation is demonstrable in another modality, then it would be possible (though not necessary) to posit a common limiting mechanism, located central to modality-specific pathways, and operating later in the processing sequence.

Method. Subjects were 30 students, 16–30 yr. old, whose participation fulfilled requirements of courses in introductory psychology. None admitted to any somesthetic deficit.

Stimuli were impacts delivered by headless 6/32 screws inserted into the driving spindles of 2 Ling (V 47, Model 102) vibration generators. Each generator was covered by a cap with a central hole of 8-mm. diameter; when *S* lightly rested the palmar surface of the middle fingertip on the hole, the finger made light contact with the screw. Two-millisecond square pulses gated a transistor which impressed 6 v. across the generator and a series resistance. There were 2 such circuits, one for each hand, the series resistances being adjusted to make the impacts on the 2 hands subjectively equal in intensity to *E*s. The distance between the screws delivering the impacts was 15 cm. The sounds made by the generators were masked by a low level of thermal noise.

Half the *S*s (9 male, 6 female) constituted the unimanual standard (US) group, and half (8 male, 7 female) the bimanual standard (BS) group. The *S*s in the US group were told that they would feel 2 4-sec. trains of taps, a standard train to the left hand, followed after a .5-sec. interval by a comparison train in which the taps alternated between the 2 hands, starting with the left. The task was to judge whether the comparison taps occurred at a rate faster than, equal to, or slower than that of the standard. A method of limits was used, the midpoint of the interval of uncertainty being taken as the point of subjective equality (PSE). The task was demonstrated in a trial using a long (2,000-msec.) standard interstimulus interval (ISI).

Three onset-to-onset ISIs were used as standards: 1,000, 250, and 100 msec. At each ISI, 5 ascending trials alternated with 5 descending trials; within a trial, the comparison ISI was varied in equal steps, each 10% of the standard. Sequencing of trials was such that effects of practice, fatigue, etc., were distributed over ISI, within and between *S*s. The conditions for the BS group were essentially the same as for the US group, except that these *S*s had to judge a unimanual comparison train relative to a bimanual standard.

The experiment was thus similar to the auditory experiment of Axelrod et al. (1968), the major differences being that in the earlier study, (*a*) a wider range of ISI was explored (1,000–25 msec.), and (*b*) the comparison ISIs in a trial varied in a logarithmic series. The linear series used here provided a denser set of comparison ISIs around the standard than that used in the auditory experiment.

Results. For each *S* for each ISI, the score $[(\bar{X}_S - \text{standard}) \times 100/\text{standard}]$ was computed, where $\bar{X}_S$ is the mean of *S*'s 10 PSEs. The score represents the percentage deviation of *S*'s mean PSE from the standard ISI. The means of these scores are given in Table 1. All 6 means are in the

directions indicating apparent slowing of bimanually alternating trains relative to unimanual ones, and each is significantly different from the corresponding standard, *ts* (14) $\geq$ 4.04, *ps* < .01. In both groups, mean percentage deviation increased monotonically as standard ISI decreased, i.e., relative slowing increased with repetition rate. With one exception in each group, both with 1,000-msec. standards, all *Ss* showed relative slowing of bimanual pulses at all standard ISIs; by binomial test, the proportion 14/15 has $p < .001$.

A separate Treatments × *Ss* analysis of variance was performed on the percentage deviations for each group. In both analyses, the effects of ISI were significant, *Fs* (2, 28) $\geq$ 11.50, *ps* < .001. For the BS group, the difference between the means at 1,000 msec. and 250 msec. was significant by one-tailed test, t (28) = 1.84, $p < .05$. For the differences between the 250-msec. and the 100-msec. conditions, and between the 1,000-msec. and the 100-msec. conditions, *ts* (28) $\geq$ 2.92, *ps* < .01. For the US group, the difference between the means at 1,000 msec. and 250 msec. was not significant; for the remaining 2 differences, *ts* (28) $\geq$ 4.48, *ps* < .01.

The mean PSEs for each group were transformed from measures of period (ISI) to measures of rate (taps per second), and the resultant group data are plotted in Figure 1. The triangles directly represent the data of the BS group, with the bimanual standards on the abscissa and their corresponding PSEs on the ordinate. For US group (circles), bimanual PSEs are on the abscissa, with the unimanual standards on the ordinate. This is the same procedure as that used in analyzing the auditory data (Axelrod et al., 1968, pp. 52–53). The line of best fit to the 6 points has a y intercept of .38 and a slope constant of .68. The light solid line represents the function obtained with clicks by Axelrod et al. (1968), with intercept = .05 and slope = .62.

Individual slope constants were calculated for the 3 data points for each *S*. The means for the 2 groups were not significantly different; the grand mean was .68, agreeing with the group data value. The difference between the grand mean and the hypothetical veridical slope (1.00) was significant, t (29) = 12.31, $p < .001$, reflecting the uniform direction and significance of the percentage deviations from zero in Table 1. Likewise significant was the difference between the obtained slope and the value (.50) which would have resulted had *Ss* systematically ignored or suppressed all the pulses from one hand during bimanual stimulation, t (29) = 6.92, $p < .001$.

The group means of the individual intercepts were not significantly different. The grand mean was .42, approximating the group data value (.38), and was significantly different from zero, the intercept of the veridical line, t (29) = 6.42, $p < .001$.

To permit comparison of these results with those of the auditory study of Axelrod et al. (1968), we calculated slopes and intercepts for each of the 40 *Ss* in that study, from the original data. The mean slope coincided with the group data value (.62).

TABLE 1

MEAN PERCENTAGE DEVIATIONS AND STANDARD ERRORS FOR ALL CONDITIONS

Standard interstimulus interval (in msec.)	Group: Bimanual standard		Group: Unimanual standard	
	$\bar{X}$	$S_{\bar{X}}$	$\bar{X}$	$S_{\bar{X}}$
1,000	9.87	2.44	−12.67	2.85
250	24.40	5.98	−14.30	2.34
100	47.07	7.30	−28.67	3.24

Note. Each mean is based on 15 scores.

The difference between the somesthetic mean and the auditory one was not significant, t (68) = 1.50, $.10 < p < .20$. The mean intercept in the auditory study was .21 (group data value .05), and the difference between the means in the 2 modalities was again not significant, t (68) = .86. Therefore, for neither of the 2 determining constants (slope and y intercept) is there reason to assume a difference between the modalities; i.e., the auditory and somesthetic lines derived from the individual data are not significantly different from coincident.

Discussion. The present results were thus strikingly like those obtained in audition. (*a*) Apparent slowing of alternating stimuli was consistent across *Ss*. (*b*) The degree of slowing (percentage deviation) increased monotonically with repetition rate. (*c*) The group data points on the plot of single-source PSE as a function of alternating rate were well fitted by a straight line, (*d*) whose slope approximated that obtained with clicks. While there was a difference of $\frac{1}{3}$ of a pulse per second between the intercepts of the auditory and somesthetic group data lines, (*e*) there were no significant modality differences between the mean slopes or mean intercepts calculated from the individual data.

Although it can be argued that analogous processes might occur in modality-specific portions of the auditory and the somesthetic pathways, the similarity of the findings in the 2 modalities is consonant with a common central limitation on the processing of bilaterally alternating stimuli. The limitation might arise from a relative inefficiency in shifting attention rapidly between spatially separated sources. In speculation on possible bases of such an inefficiency in audition, it has been suggested (Guzy & Axelrod, 1972; Kahneman, 1970) that breakdown in attention shifting may be due to inability of motor orienting responses to follow the stimulus-alternation rate; such a mechanism would operate equivalently in audition or somesthesis, and generate parametrically similar results in the 2 modalities.

An alternative approach comes from the demonstration by Bregman and Campbell (1971) that *Ss*, listening to a repeated sequence of 6 tones (a subset of 3 high-pitch, interdigitated with a subset of 3 low-pitch, tones) presented at 10 per second, split the sequence into 2 subjectively segregated, nonintegrable streams—a high and a low. Auditory

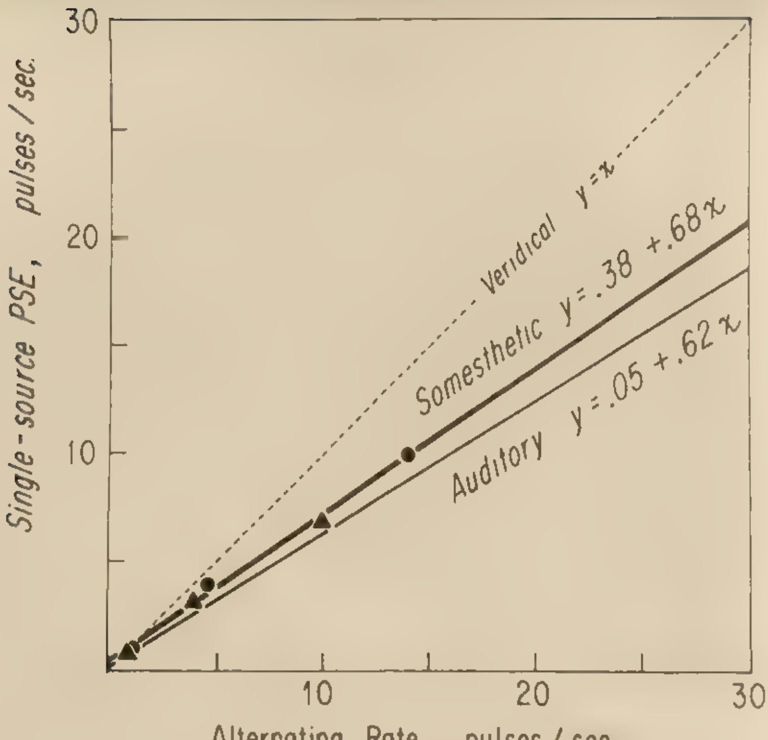

FIGURE 1. Single-source point of subjective equality (PSE) as a function of alternating-source rate. (The heavy line represents unimanual PSE as a function of bimanual rate [group data], and is the line of best fit to the data points. Triangles: bimanual standard group. Circles: unimanual standard group. The light solid line is the line of best fit to the auditory-click data of Axelrod, Guzy, and Diamond, 1968.)

and somesthetic slowing of bilaterally alternating trains may reflect an inability to integrate the results of similar segregations into left and right streams, a possibility which could be tested by using variants of the Bregman–Campbell paradigms with ear or body-side subsets, rather than pitch subsets. Stream segregation by spatial location appears to have been implied in von Békésy's (1959) early observations that when white-noise bursts are presented alternately between widely spaced speakers, or between widely spaced somesthetic stimulators on an arm, the observer can attend to one or the other source, but not simultaneously to both.

So far as neural substrate is concerned, 2 types of account of the present results suggest themselves. One would involve a central mechanism which is less able to integrate bilaterally alternating stimuli than to process single-source stimuli, e.g., because of greater refractoriness to alternating than to unilateral inputs. A mechanism of this sort would presumably be located in an area receiving both auditory and somesthetic information, such as association cortex (Thompson, Johnson, & Hoopes, 1963) or superior colliculus (Wickelgren, 1971). Another possibility is contained in Holden's (1973) suggestion that difficulty in integrating alternating stimuli is a function of the disparateness of the cortical projections of the stimulus subsets. This hypothesis is especially attractive in being testably applicable to many dimensions from which subsets can be drawn —e.g., ear, pitch, location in auditory or visual space, body locus, and sensory modality.

LEARNER JUDGMENT IN INSTRUCTIONAL DECISIONS FOR LEARNING MEANINGFUL PAIRED ASSOCIATES[1]

M. I. CHAS. E. WOODSON[2]

University of California, Berkeley

The problem studied is the facilitation of the learning by college students of meaningful paired associate lists consisting of pairs of romanized Japanese words and corresponding English words. Six instructional strategies differing in the method of determining the frequency of item occurrence were evaluated experimentally. The strategies differed in that during instruction, the next item was (*a*) randomly selected, (*b*) randomly selected with item frequencies balanced to give more training on difficult items, (*c*) randomly selected from among items that had not been correctly responded to twice consecutively, (*d*) learner selected where learners received no instructions about selection, (*e*) learner selected where learners were told to select items they did not know, and (*f*) learner selected where learners were told to select items they knew. Learning, as measured by a retention test 1 wk. later, was superior for the sequences which lead to high error rates during instruction, whether or not they were learner selected or computer selected. Learner's judgment can be used to increase instructional effectiveness during instruction and can be made more effective by instructions to the learner. Implications for instructional theory are discussed.

Atkinson (1972b) has reported an experiment in which a model for computer-selected instructional sequences was found to be more effective than learner-selected or randomly determined instructional sequences. Atkinson found learner selection of instructional sequences considerably less effective than a computer model based on a theory of learning which postulates 3 states of learning and used transition probability matrices, estimated for each item, for state changes when an item is responded to correctly and when another item is missed. One might take the position that his learners were handicapped in their selection by not following the general instructional strategy used by the computer model, that is, that it is most effective to study those items which one does not know very well. The average number of errors during training show *Ss* drilled themselves on relatively learned material about midway between the most difficult and easiest computer-selected sequences, perhaps out of motivation to get a higher score during instruction or perhaps out of the general habit of opting to respond to what one feels one knows, a habit which is probably taught indirectly in school.

The instructional strategies discussed here may be considered schemes for the allocation of instructional trials among items. The basic strategy is to allocate more trials to unlearned items and fewer to learned items. Presumably if the learner is able to select those items which he does not know and those which he knows, his judgment would be very valuable as a basis for the allocation of instructional trials among items.

The purpose of the present study is to examine the question of whether learner-selected instructional sequences can be made more effective if the learners are given specific suggestions about a general strategy for selecting their instructional experiences.

Method. The *Ss* were 120 undergraduate students; 20 *Ss* were assigned randomly to each of 6 instructional conditions and were instructed individually. None of the *Ss* had prior course work in Japanese and none professed familiarity with the language.

The instructional materials were 50 romanized Japanese words paired with English words. The pairs included 30 nouns, 11 verbs, and 9 adjectives, and were selected to have nearly equivalent meanings in the 2 languages. The words involved simple everyday terms (uchi, house; yoru, night), in most cases having 4 or 5 letters. The 50 Japanese words were divided randomly into 5 subsets of 10. The order of words within these 5 subsets was randomly determined for each *S* and these lists were before *S* during the training sessions.

The *Ss* participated in 2 sessions: an instructional session which lasted approximately 2 hr. and a test session, 1 wk. later, which lasted about 20 min. The instruction was conducted by teletypewriters and an HP2000B computer (Hewett-Packard) time-sharing system.

The instructional session involved a series of self-paced trials, each involving a response to a particular item. Each *S* had before him, mounted for easy reading on the teletype terminal, 5 lists of Japanese words which remained in view throughout the training period. The instructions to *S* explained that he must respond to one of the items from each of the lists in sequence from list to list. In the computer-controlled sequences this was automatically con-

TABLE 1

Proportion of Correct Responses in Successive Trial Blocks during the Instructional Session and on the Retention–Transfer Test Administered One Week Later

Condition	Successive trial block (instructional session)					Test
	1	2	3	4	5	
R	.15	.41	.61	.65	.70	.40
RD	.07	.17	.27	.24	.32	.80
RU	.05	.10	.14	.13	.19	.79
LS	.11	.20	.27	.32	.36	.52
LSK	.30	.41	.37	.50	.67	.22
LSU	.03	.06	.12	.10	.15	.85

trolled as the computer selected the next Japanese word. In the learner-selected conditions this was not controlled, but a spot check indicated *S*s were highly reliable in following this procedure.

In all instructional conditions *S* responded by typing the Japanese word, a blank, and the English word. If the response by *S* was correct, the system proceeded to the next item. If the response by *S* was incorrect, the system crossed out his answer and typed the correct answer, thereby providing feedback regarding *S*'s responses. The 6 experimental groups were distinguished by the way the next item was selected for instruction:

In the random order (R) condition, the next item was selected randomly (without replacement) from the appropriate sublist of Japanese words.

In the random order balanced for difficulty (RD) condition, the next item was selected randomly with the item distribution balanced to make more difficult items occur more frequently. Data from Condition R were used to estimate the mean trials to learning for each item, and the distribution was selected to attempt to equalize for all items the probability of learning during training.

In the random order unlearned (RU) condition, items responded to correctly twice in a row were considered learned by *S*. The next item during instruction was selected from among the items which had not been answered correctly 2 consecutive times.

In the learner-selected (LS) condition, *S* selected the next Japanese word to answer from the appropriate sublist.

The learner-selected known (LSK) condition was the same as LS except *S* was told that previous research had shown it was more effective to practice items he knew to "strengthen their retention" or "try items he thought he knew rather than items of which he was completely unsure," and "to only try items he was unsure of when others were learned very well."

The learner-selected unknown (LSU) condition was the same as LS except *S* was told that previous research had shown that it was more effective to study those items he did not know because "partly known items tended to be almost learned but completely unknown items required quite a bit of practice to get them to the stage where ... was any chance of remembering them."

In all conditions, before instructio... in *S*s typed all 50 Japanese words and En... words from a list provided him.

The retention test, conducted approxi... 1 wk. later, was the same for all *S*s and consist... ittoed sheets with all 50 Japanese words studi... he *S*s were instructed to write the correspond... nglish term for each.

Results. The results of the experime... summarized in Table 1. The first 5 colum... of the table present the proportions correct du... learning; the sixth column presents data from ... retention test. The data from the instructio... ession are presented in 5 successive blocks of 50 tr... each; for the R condition this means that each ...em was presented once in each of these blocks. ...e table gives point estimates of the parameters ...volved. All possible pair-wise comparisons amo... group means were calculated with an overall ...or rate set at .05 within measures by means of th... Bonferroni inequality procedure using the *t* statist... (Miller, 1966). The pooled within-cell variance... or Trial Blocks 1–5 and the retention test were ...5, .010, .029, .041, .047, and .032, respectively. T... following conclusions are based on those compa...ons that indicated statistically significant differen...

In terms of average proportion corre... during training, the conditions may be ordered ... = LSK > LS = RD > RU = LSU. In the LS, ...K, and LSU conditions, the error rates during in...ruction follow the anticipated pattern, indicating ...ost *S*s followed their instructions.

The order of the experimental groups on the retention test is nearly the reverse of that of errors during training. The pair-wise comparisons on the retention scores lead to the order LSU = RD = RU > LS > R > LSK in instructional effectiveness.

The RD, RU, and LSU conditions involve a procedure that attempts to identify and instruct on those items that have not yet been mastered and therefore should produce high error rates during the instructional session.

The magnitudes of the effects observed on the retention test are large enough to be of practical significance. The LSU condition (when compared to the R condition) leads to a point estimate of relative gain of 112.5% in terms of items correct on the retention test. It is clear that *S* can be very effective in determining an efficient study sequence, as effective as the adaptive instructional system used here, and can be made more effective by appropriate instructions.

Discussion. The results show that learning of meaningful paired associates can be facilitated to a considerable degree by some simple instructions to the learner.

On the other hand, it may also be argued that this task does not test the learner-controlled notion very effectively. Learners were probably primarily following the instructions they were given. Factors which have been claimed to affect learner-controlled

sequences such as motivation, learner inquiry, and the use of learner judgment about his own understanding have relatively little opportunity to be effective in the present task.

As in Atkinson's (1972b) study, there is an inverse relationship between proportion correct during learning and proportion correct during testing. This suggests some caution in the popular custom of using trials to criterion or number of errors during instruction as measures of learning in paired-associate studies, particularly when the instructional procedure is sensitive to responses by the learner.

The LSU, RD, and RU strategies were not distinguished on the retention score; the confidence intervals associated with the contrasts were $.05 \pm .18$, $.06 \pm .18$, and $.01 \pm .18$, indicating that whatever differences there may be among these 3 are small compared with the differences between these strategies and the others tested.

Atkinson's (1972b) finding that automated procedures can facilitate learning to a degree of considerable practical significance is supported by the present study. But this study also implies that appropriate instructions to learners can also facilitate learning to a degree of considerable practical significance. Presumably we will be able to design automated instructional devices which are more effective than procedures which the learner himself can implement; but they will have to be more effective at inferring the degree of learning of individual items, and selecting appropriate instructional experiences and sequences, than the learner himself when the learner has the benefit of as much knowledge about the task as that used to design the automated device.

This study does not contradict Atkinson's (1972a) conclusions that learner control may be one source of information in making instructional decisions, but complete dependence upon learner judgment is not warranted. Learner judgment may be an important component in instructional models. Obviously it expends time and other resources, but the exercise of learner judgment may itself result in learning; and this study demonstrates that learner judgment can be used to obtain more efficient instruction than random selection of instructional sequence. Instructional models will no doubt be developed which use learner judgment as a part of the information upon which instructional decisions are based, but it remains to be seen whether the costs associated with this procedure exceed the gains.

This study shows that learners can be taught to more effectively use learner judgment for instructional decisions.

CHOICE AS A DISRUPTER OF PERFORMANCE IN PAIRED-ASSOCIATE LEARNING[1]

LAWRENCE C. PERLMUTER[2]

Bowdoin College

RICHARD A. MONTY

Human Engineering Laboratory, Aberdeen Proving Ground, Aberdeen, Maryland

PETER M. CROSS

Bowdoin College

In 2 experiments, half of the *S*s were permitted to choose their responses from alternatives following the 1971 procedure of Perlmuter, Monty, and Kimble. The other *S*s were forced to learn the responses chosen by their yoked masters. Both groups of *S*s were forced to learn an interposed A–C list following the choice–force procedure but prior to learning the A–B list. The performance of force *S*s was reliably superior to that of choice *S*s on A–C; however, when both groups learned A–B, the typical facilitative effect of choice was disturbed. In a second experiment, interposing a C–D list produced equivalent performance in both groups on C–D. Similarly, the facilitative effect of choice was not observed on the subsequent A–B trials. The degraded performance of choice *S*s was discussed in terms of frustration as an additional source of motivation.

Allowing *S*s the opportunity to choose a portion of the response materials to be learned on a subsequent paired-associate list was examined with a paradigm that manipulated both the amount of choice allowed during the selection procedure and the locus or point at which choice took place (Monty, Rosenberger & Perlmuter, 1973). The amount of material chosen is not as important as the point at which choice is exercised, as indicated by the finding that even when only 3 out of 12 items were chosen, performance on the entire list was nearly as good as that when all 12 items were chosen, provided that choice was allowed early in the experiment. Such an observation ruled out the associative interpretation of the choice vs. force phenomenon as suggested by Perlmuter, Monty, and Kimble (1971) and seemed to favor a motivational explanation. Subsequently, Perlmuter and Monty (1973) found some preliminary evidence that motivational factors may even work in a detrimental fashion under certain conditions.

A rather extensive literature exists on the relationship between motivational level and performance. It is generally asserted that performance increases as motivation increases. However, excessively high levels of motivation have also been implicated in a deterioration of performance (Brown, 1961). Thus, the purpose of the present experiments is to study further the role of choice in learning and to examine the possibility that choice may have an inhibitory as well as a facilitatory effect on performance.

Experiment I

Employing the basic design of Perlmuter et al. (1971), half of the *S*s chose their A–B responses (choice group), while the other *S*s were forced to learn those responses chosen by their yoked masters (force group). In contrast to earlier experiments, an A–C list was forced upon both groups prior to the learning of A–B, with the expectation that inhibitory effects would cause the choice group to be inferior to the force group on A–C trials, while motivation produced by prior choosing would cause them to be superior to the force group on the subsequent A–B trials. Thus, the analysis of the A–B trials should serve to determine the durability of the beneficial effect of choice.

Method. The *S*s were 40 male and female University of Delaware students, aged 19–25 yr., who were paid $2.00 each for participating in the experiment. They were alternately assigned to 2 groups of 20 *S*s each in order of their appearance.

The apparatus and general procedures were identical to those employed in previous studies. Briefly, the last 84 5-letter words were taken from a list generated by Taylor and Kimble (1967) and were considered to be of relatively high meaning. These items were assembled into 12 groups of 7 each. Within each group, one item was designated arbitrarily as the stimulus word and one item as the A–C response word. The remaining 5 items served as the 5 potential response words on the A–B list. Each *S* was first presented with 3 paired-associate (PA) practice trials utilizing common words. The choice group was then presented with 12 slides, one at a time. Each slide contained a stimulus word centered on the left and 5 potential response words listed vertically on the right. The *S* was instructed to read the stimulus word and the 5 potential response words aloud and to then select

[1] This research was supported in part by Grant MH-15315 from the National Institute of Mental Health to the first author. Experiment I was presented at the meeting of the Southeastern Psychological Association, New Orleans, May 1973.

[2] Requests for reprints should be sent to Lawrence C. Perlmuter, who is now at the Department of Psychology, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061.

one word to serve as the response word to the particular stimulus in a subsequent PA learning task. Each S went through the 12 slides at his own rate.

Immediately upon completing the selection of the response items, Ss were informed that they would be required to learn an A–C list prior to the A–B list. The A–C trials were comprised of the stimuli viewed during the selection process, and these stimuli were paired with the E-selected response words indicated above. The stimulus and stimulus-response slides were shown for 2 sec. each. The interval between slides was approximately .9 sec. The S was instructed to say the appropriate word aloud upon presentation of each stimulus slide, and E recorded S's verbal responses.

There were 10 presentations of the 12-word A–C list in 3 different random orders. Each order was presented on every third trial, and each S viewed all items in the same order. A brief period of about 2 sec. followed every third presentation of the list to enable E to return the slide tray to its starting position.

The A–C list was then followed by 10 PA learning trials, with pairs comprised of the stimulus words along with S-selected responses. This A–B list (also presented in 3 different random orders) followed the A–C list after a delay of approximately 50 sec., which was necessary to change slide trays on the projector. The Ss were informed about the change in the list just prior to the A–B trials.

The force group was treated identically to the choice group except that, although they read the stimulus and potential response words aloud, they were not given the opportunity to choose their own responses. Rather, following their reading, they were assigned the response words chosen by the previously tested choice S while each slide was still visible to them. During the choice–force procedure, both groups viewed the slides for approximately 15 sec.

Results and discussion. The number of words correct per trial served as the measure of performance on all analyses. The data for the first A–C trial were omitted from this analysis of variance as all scores were zero. Both trials, $F\ (8,\ 304) = 149.00$, $p < .001$, and the Trials × Groups interaction, $F\ (8,\ 304) = 2.35$, $p < .05$, reached significance, while the groups effect did not. The data underlying the interaction are shown in Figure 1. It can be seen that the force group performed consistently better than the choice group, and that the magnitude of the difference tended to increase generally as a function of trials. This finding is in sharp contrast with the earlier findings (Monty & Perlmuter, 1972; Monty et al., 1973; Perlmuter et al., 1971), all of which indicated that when A–B learning immediately follows the choice procedure, the choice group performs significantly better than the force group, presumably as a result of enhanced motivation stemming from having had the opportunity to choose. However, these results are supportive of Perlmuter et al. (1971), who found

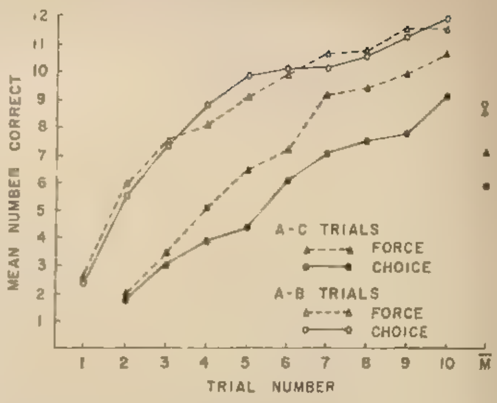

FIGURE 1. Mean number of correct responses on the A–B and A–C trials for the choice and force groups (Experiment I).

that performance on a nonchosen A–C list that was learned following A–B was poorer for choice Ss than for force Ss.

Theoretically, it may be possible to account for the degraded performance of the choice group on the A–C trials in terms of a nonoptimal increase in motivation caused by the interposition of the A–C trials. That is, the additional source of motivation might be thought of as frustration or thwarting (Brown, 1961) caused by the forced learning of the nonchosen A–C list following an opportunity to choose the A–B responses. For force Ss, neither the A–B nor the A–C lists are chosen; hence this frustrative source of motivation should not manifest to the degree that it does for choice Ss. Intrusion data provide further evidence for this interpretation, since increased motivation presumably increases the frequency of competing responses. The choice group made reliably more intrusions (311) than the force group (145), and 87% of the intrusions in each group were misplaced A–C responses. In addition, the finding that choice Ss tend to perform more poorly whether the nonchosen A–C list follows (Perlmuter et al., 1971) or precedes the chosen A–B list lends generality to the proposal that forced learning induces a nonoptimal level of motivation and hence degrades performance.

Finally, when both groups begin to learn the A–B list (following A–C), it would be expected that the incremented motivational level of the choice group would be reduced to a more favorable level. Presumably, the beneficial effect of choice would manifest itself on A–B. In view of the fact that there were differences between groups on the A–C list, however, this analysis must be treated with caution, as discussed by Perlmuter et al. (1971). Only the main effect for trials reached significance, $F\ (9,\ 342) = 142.24$, $p < .001$, indicating a general improvement in performance across trials. As is evident from an examination of the upper 2 curves in Figure 1, the performance of the choice and force groups was highly similar across trials. Thus, it appears as if the beneficial effect of choice noted in previous investigations is destroyed when an

intervening forced list is interposed prior to the learning of A–B. Whether the A–C list enhances the performance of the force group or diminishes the performance of the choice group cannot be ascertained from this experiment.

Experiment II

We have just seen evidence which suggests that A–C trials interpolated between choosing A–B responses and learning the A–B list lead to a deterioration in performance. The nature of the interpolated materials to be learned may be important in the production of this effect. That is, it is entirely possible that an interpolated C–D list may not produce the same degree of frustration that an A–C list might produce. This may be attributable to the degree of formal similarity between A–B and A–C as contrasted with A–B and C–D. Whether the relationships just discussed also determine the performance of the choice and force groups on the subsequent A–B trials will have to await empirical test. Thus, the purpose of Experiment II was to repeat Experiment I, substituting a 10-item C–D list for the A–C list employed in the latter.

Method. The *S*s were 40 male and female students from Bowdoin College. The apparatus and procedures were generally identical to those of the first experiment except that the A–B list was a 12-item high-meaning list similar to that employed in Experiment I, while the C–D list was a 10-item low-meaning list. The A–B list was generated from 72 of the last 75 stimuli on the Taylor and Kimble (1967) list, while the low-meaning C–D list was selected from the first 102 stimuli of the same list. As opposed to Experiment I, 12 rather than 10 trials of each list were presented.

Two groups of 20 *S*s each were run. A C–D choice group was treated identically to the choice group of Experiment I except that following the A–B choice procedure, choice *S*s were required to learn the C–D list, after which they learned the original A–B list. The *S*s in this group were informed of the fact that they would learn A–B (as in Experiment I) after learning C–D. The C–D force group also learned the C–D list before learning the A–B list and was forced to learn the A–B response chosen by the previous *S* in the C–D choice group.

Results and discussion. Performance on the interposed C–D trials (2–12) by the C–D choice group and C–D force group was evaluated. Trial 1 was eliminated from the analysis because there were no correct responses. Only the trials effect reached significance, F (10, 380) = 69.96, $p < .001$, while groups (mean number of correct responses per trial = 2.50 for the C–D choice group vs. 3.00 for the C–D force group) and the Groups × Trials interaction were clearly not significant.

To test the effect of the interposition of the C–D list on A–B learning, performance of the C–D choice group vs. the C–D force group was compared across the 12 A–B trials. The C–D choice group averaged 10.06 correct responses per trial, while the C–D force group averaged 10.08 correct responses per trial. Again, only trials reached significance, F (11, 418) = 87.79, $p < .001$, and the F values for groups and the Groups × Trials interaction were both less than 1.00.

Thus, the results of the present experiment are important in clarifying 2 major points raised by Experiment I. First, when a nonchosen list is imposed upon choice *S*s following their selection of A–B responses, it appears that the similarity of the chosen and nonchosen materials is a critical factor in producing the frustrative effects presumed to have been engendered by the forced list. This conclusion derives from the fact that an interpolated C–D list is learned equally well by C–D choice and C–D force *S*s immediately following the choice-force procedure, which is in marked contrast to the superiority of force *S*s (Experiment I) on A–C. Second, the interposition of a C–D list is sufficient in disturbing the superiority of choice *S*s on A–B. This result is important in substantiating the similar effect observed in Experiment I, in which an A–C list was interposed, but does so under conditions in which first-list learning was not different in the groups subjected to the choice or force procedure. Of course, it is possible that the passage of time is responsible for the equalization of performance on the A–B trials rather than the effect resulting from the interposition of either the A–C or C–D list. This alternative cannot be ruled out completely; rather, it suggests the necessity of determining the temporal stability of the often observed beneficial effect of choice.

MNEMONIC TRANSFORMATIONS AND VERBAL CODING PROCESSES[1]

RAYMOND W. KULHAVY[2] AND JAMES R. K. HEINEN

Arizona State University

Verbal coding research has generally concentrated on parameters of specific mnemonic processes. It appears that many such devices can be explained in terms of some smaller set of control transformations required to accomplish them. Learning of a categorized noun list under serial and total presentations was compared across 4 types of mnemonic coding instructions: imagery, clustering, narrative, and learn. The imagery group had the highest total recall over 3 trials, in spite of clustering *S*s' superior organization. Serial presentation generally enhanced learning and was highly facilitative for the imagery serial group. Results supported the contention that effects of mnemonic instructions on learning are a function of the type of coding transformation necessary to produce them.

Studies of verbal coding processes have concentrated on identifying the parameters of specific control procedures such as imaging, language mediators, prose chaining, and organizational strategies. Essentially, it appears that the majority of known coding mechanisms can be expressed in terms of some smaller set of functional transformations necessary to produce them. Furthermore, one can argue that not only are these transformations necessary for encoding to occur, but they are, in fact, the primary vehicle for transfer of verbal input into long-term memory.

There seem to be at least 2 types of transformational controls that operate when encoding takes place. The first of these we have labeled a *unit* transformation. Unit transformations occur when *S* defines the functional characteristics of verbal stimuli by direct elaboration. For example, if the stimulus is a specific word, *S* might elaborate by placing the word in a visual representation (an image), adding additional language components directly to the word (syntactic mediation), or embedding the word in some semantic context (a narrative).

We will call the second process an *order* transformation. Order transformations accomplish encoding by performing sequence and grouping changes on the input stimuli. In other words, functional characteristics become class dependent. Studies of category clustering are exemplars of this transformation mode.

Of the 2 transformation processes hypothesized, order transformations seem to be the more complex. With unit transformations, *S* simply selects the most available and salient coding vehicle, embeds the new materials within it, and stores the resulting fused compound in memory. In the case of order transformations, however, 2 types of coding information are required for efficient storage. First, *S* must select some primary storage classification (category, superordinate, etc.), and second, he must rearrange the input to match the class chosen. This hypothesis is buttressed by research showing higher recall levels for *S*s who receive category classes as a part of the input information (Tulving & Pearlstone, 1966), allowing a bypass of the first step in the process. The more complex order transformations would, of course, entail treating entire sets of transformed elements as single components in some new ordering strategy.

On the basis of our reasoning, we would predict that instructions to use less complex unit transformations should lead to higher recall scores than instructions to use more complex unit or order transformations—even when the words learned consist of well-defined category sets. If the complexity hypothesis is valid, measures of order transforming (i.e., clustering) should be significantly greater for order-instruction *S*s, in spite of inferior total recall performance.

Finally, a test of the transformation notion would result if stimulus presentation mode were varied. When items are presented singly, unit transformations should be facilitated simply because each item can be processed and stored individually. However, when the list is given en masse, one would predict an advantage for order-transformation instructions, since ease of selecting appropriate primary coding classes would be increased.

Method. Two factors, preexperimental instructions (imagery, clustering, narrative, and learn only) and presentation mode (serial or total) were combined factorially to form 8 treatment groups. Trials were varied as a within-*S*s variable across each factorial cell. The design was thus a 4 (Instructions) × 2 (Presentation Mode) × 3 (Trials) mixed analysis of variance, with repeated measures on the Trials variable.

The *S*s were 83 undergraduate volunteers, randomly assigned to the experimental conditions in order of their appearance for the experiment. Three *S*s were dropped from the study for failure to follow procedural instructions.

The stimuli were 20 nouns selected from the Battig and Montague (1969) category norms. Five

Note. Each mean is based on the recall performance of 10 *S*s.

words were chosen from each of the following 4 categories: insects, natural earth formations, seasonings, and sciences. All words were selected from between the third and fourth associative-frequency quartiles for each category. The 20 words were assigned randomly to list position, and were typed on either 3 × 5 in. filing cards or on white foolscap as a triple-spaced list.

During the experimental sessions, *S* sat across a table from *E* and was read verbal instructions appropriate to his treatment. Following instruction, *S* was shown 3 sample items, either serially or together, as an example of the task required.

Imagery *S*s were told to form mental images of each word; clustering *S*s were asked to group the 20 items into common categories; narrative *S*s were directed to chain the words together sequentially in a "short story" that was meaningful for them; and learn-only *S*s merely said each word aloud during presentation.

For serial *S*s, *E* exposed each of the 20 cards at a 3-sec. presentation rate. Speed of exposure was controlled by beeps from a tape recorder. In the total list conditions, *S* was presented with the entire list for 60 sec. Again, time was counted from the taped beeps. To eliminate direct recall from short-term memory, *S*s were required to solve a page of complex arithmetic problems following presentation. The interpolated task was continued for exactly 1 min. Finally, *S* was given a sheet of lined paper and a 2-min. period to free recall as many of the 20 nouns as possible. This procedure was replicated exactly for each of the 3 trials. Following completion of Trial 3, *S* was given a questionnaire assessing the degree to which he had used the appropriate learning strategy.

Recall protocols were scored for total recall, with minor spelling errors counted as correct. Degree of organization was calculated for each recall, using Bousfield's (1953) ratio of repetition (RR). Perseveration errors were discounted in the calculation of RR.

Results. Table 1 presents item-recall means and standard deviations for instructional conditions and presentation modes for each of 3 trials. A 4 (Instructions) × 2 (Presentation Mode) × 3 (Trials) analysis of variance yielded significance for the main effects of instructions, F (3, 72) = 4.63, $p < .01$, and Trials, F (2, 144) = 580.88, $p < .01$, and the Instructions × Trials interaction, F (6, 144) = 2.53, $p < .05$. Comparisons among the instruction means using Scheffé's test showed that imagery *S*s recalled significantly more words than the other treatment groups ($p < .05$). Recall performance of learn-only *S*s was significantly below that of the 3 transformation conditions ($p < .05$). The Instructions × Trials interaction occurred simply because the 3 transformation groups showed a negative acceleration in recall gain for Trials 2 and 3, whereas performance of the learn-only controls was linear due to a lack of ceiling effects. Presentation mode failed to contribute significantly to recall performance.

To assess the degree of order transformation, RR was calculated for each *S* on every trial. Table 2 gives RR means and standard deviations for the instruction and presentation mode conditions across trials. A 4 (Instructions) × 2 (Presentation) × 3 (Trials) analysis of variance was significant for the main effects of instructions, F (3, 72) = 11.57, $p < .01$, presentation mode, F (1, 72) = 5.28, $p < .05$, and Trials, F (2, 144) = 17.00, $p < .01$, and the Instructions × Trials F (6, 144) = 29.00, $p < .01$, and the Instructions × Presentation Mode × Trials, F (1, 144) = 5.50, $p < .01$, interactions. A Scheffé test among the instruction means showed clustering *S*s having a significantly higher RR than the remaining 3 groups ($p < .05$). No other post hoc comparison reached significance. The Instructions × Trials interaction shows that neither the learn-only nor narrative group increased RR appreciably over trials. Imagery *S*s demonstrated a slow rate of climb, and clustering *S*s show a negative acceleration in Trial 3, probably due to both ceiling effects and the restrictive parameters of RR itself (Shuell, 1969).

Discussion. These data are essentially supportive of our model. The learning of a discrete noun list is

TABLE 2

MEANS AND STANDARD DEVIATIONS (IN PARENTHESES) FOR RATIO OF REPETITION

	(.04)	(.04)	(.05)	(.05)	(.02)	(.04)	(.02)	(.04)

facilitated by instructions to transform the items in a specific manner prior to storage. Furthermore, the recall power of such instructions can be predicted from the type of transformation required. The imaginal unit manipulation led to greater facilitation than did either the more complex narrative or order transformations. This finding occurred in spite of the superior organization scores of clustering *S*s.

Differences in item recall as a function of presentation mode did not occur as predicted. It appears possible that input variables are not as important for transformation processes as we assumed. It may be that *S*s tend to treat total list items as single units—transforming them sequentially rather than selectively.

The Instructions × Presentation Mode × Trials interaction provides some interesting results. The reversal of the clustering group performance across trials is clearly due to serial *S*s' lack of an efficient order strategy on the first trial. However, on later trials, organization surpassed that of even the total list group once categories were learned. A more critical point concerns the organization performance of imagery *S*s who received the serial list. The high RR scores for these *S*s on Trials 2 and 3 suggests a tendency to use *both* unit and order transformations to accomplish encoding. Data from the post-experimental questionnaire indicate that these *S*s first transformed the words in a unit fashion, using images, and then began to link the units together, using an order transformation. For example, one *S* in the group responded "first tried to form pictures . . . then saw them together (like) a *katydid* fighting a *mite*. . . ." Here, the unit-transformed images are interactively combined under the category "insects." Several *S*s reported attempts to link the words in some fashion once they had formed the images. Such multiple transformations should result in a high probability of images in the same category being recalled together—exactly the effect shown by our data. In this case, serial presentation may have expedited the multiple-transformation process in an effort to code rapidly or to reduce the load on memory.

The results of this preliminary study are highly suggestive that research on the transformation process will prove profitable. If we are able to isolate the effects of transformations as they occur singly and together in natural language, we will have gone far in explaining the processes underlying human verbal behavior.

TIME-OF-OCCURRENCE CUES FOR "UNATTENDED" AUDITORY MATERIAL

STUART T. KLAPP[1] AND PATRICIA LEE[2]

California State University, Hayward

When *S*s shadow (repeat aloud) an auditory message arriving in one ear, memory for material arriving in the other ear falls off over a few seconds of presentation-to-recall delay. Contrary to Glucksberg and Cowen, however, *S*s can accurately estimate the length of delay from the time of presentation of an item in the nonshadowed ear to the time at which the recall signal occurs.

In the shadowing experiment, *S* repeats aloud (shadows) what is heard in one ear while additional material is presented in the other ear. Much interest has surrounded the fate of the material that is not shadowed—the so-called "unattended" material. Although there seems to be little if any long-term memory (LTM) for this material, as assessed by recall at the end of a period of shadowing, short-term memory (STM) may be present (Glucksberg & Cowen, 1970; Norman, 1969). The present investigation focused on one alleged property of STM for nonshadowed material—the possible lack of time-of-occurrence information. Glucksberg and Cowen had *S*s recall digits that were embedded in prose and presented to the nonshadowed ear. A signal light indicated that *S* was to stop shadowing and attempt to recall the digit. The presence of STM without appreciable LTM was shown by a rapid decrease in digit recall as the digit-to-signal delay increased over a few seconds. The *S*s were also asked to "estimate the distribution of delays between digit occurrences and onsets of the cue light [p. 154]" and they "uniformly reported that there had been no delays; either a digit had occurred contiguously with or just before a cue light, or the cue light had flashed alone [p. 154]." This finding led the authors to conclude that memory for nonshadowed material does not contain "time tags." This is indeed a remarkable property for STM and would seem to justify further investigation. However, one must view this conclusion with caution, since *S*s were asked to estimate these delays in terms of a distribution for the entire session, rather than individually for each trial. The purpose of the present experiment was to assess in a more sensitive manner whether *S*s can judge the length of the digit-to-cue delay.

Method. The present experiment attempted to replicate the Glucksberg and Cowen (1970) procedure in all essential features, except that *S*s were asked to estimate the length of the delay from digit presentation to recall cue after each trial rather than to estimate the distribution of these delays at the end of the experiment. It was assumed that this change in procedure would yield a more sensitive estimate of the extent to which *S*s were aware of the time at which the memory digit was presented.

Six right-handed students who reported normal hearing and English as their native language served as *S*s in order to fulfill an introductory psychology course requirement at California State University, Hayward. Before serving in the main experiment, each *S* received 1 min. of practice in shadowing prose in the presence of a distracting message in the other ear.

The message to be shadowed was a passage of English fairy tales, while the nonshadowed message was taken from *David Copperfield* and contained embedded test digits. Both 32-min. messages were read in the same female monotone at 160 words/min. For half of the *S*s, the material to be shadowed appeared in the right ear. The timing relationship between the embedded test digits and the cue light was obtained by recording inaudible signal pulses in one channel of a 2-track tape recorder such that these pulses followed the test digits in the other track by predetermined intervals. These signal pulses triggered a white cue light which was *S*'s signal to stop shadowing and recall the digit. Test digits were randomly selected from the digits 1–9, eliminating the 2-syllable digit 7. All other digits and digit homonyms were eliminated from both prose passages.

Trials were presented in 2-min. blocks, with each block of trials containing all 6 delays (0, 1, 2, 4, 8, and 16 sec.) presented in a random order. The delay from the recall cue of the preceding trial to the introduction of the next test digit was approximately 15 sec. Each *S* received 16 blocks of 6 trials. The *S*s were instructed to stop shadowing when the cue light appeared and to recall any digit recently heard. Although *S*s were encouraged to guess what the digit was, they were not required to respond on each trial. They were also to estimate the delay time from digit to signal light by calling out an estimate of 0–16 sec. each time a digit was recalled.

Results. In agreement with Glucksberg and Cowen (1970), digit recall was approximately 25% at minimum cue delay and decreased at longer delays, $F\ (5, 25) = 2.61$, $p < .05$. As is clear from Table 1, the asymptotic level of recall was higher in the present experiment, but this may be attributable to differences in chance levels in the 2 experiments (S. Glucksberg, personal communication, October 1972). In the present experiment,

[2] Now at Michigan State University.

smaller set of digits was used, and there were no "blank" trials in which a cue light appeared when there had been no digit. Unfortunately, it is difficult to assess the chance level in either experiment, since *S*s were not required to respond on each trial. Such a procedure would have been useful for purposes of analysis, but would seem unnatural to *S*s, who frequently reported that no digit at all had been heard. Regardless of these details, it seems reasonable to conclude that the decaying STM for unattended digits has been replicated in the present experiment, so that it appears that the same basic phenomenon is being investigated.

Considering only those trials on which digit recall was correct, *S*s' estimates of the cue delays were highly correlated with the actual delay from digit to cue light, $r = .90$, $p < .001$. Furthermore, 76% of the estimates were not more than 1 sec. different from the actual delay, while 32% of the estimates were identical to the actual delay.

Discussion. The present results provide no support for the assertion of Glucksberg and Cowen (1970) that time cues are missing from STM for nonshadowed material, but rather demonstrate that time-of-occurrence estimates can be made with great accuracy. Having eliminated the alleged [illegible] of time cues as a property of STM for non-shadowed material, there appears to be no reason [illegible] assume that STM for nonshadowed material is different from STM in the distractor paradigm of Peterson and Peterson (1959). In both cases, recall falls off dramatically after only a few seconds [illegible] activity. The lower initial recall of nonshadowed material compared to the initial recall in the distractor paradigm can be attributed to reduced perceptibility of the to-be-remembered items in the presence of the sound and the verbal [illegible] of shadowing. However, forgetting of perceived items may be assumed to follow the same laws in both cases in the absence of evidence to [illegible].

[illegible]shadowed material seems to be understood even though it is not remembered for long. Corteen and Wood (1972) observed galvanic skin responses to names of cities in the nonshadowed channel when other city names had previously been associated with shock. Lewis (1970) found that the reaction time to repeat (shadow) a word was a function of its semantic relationship to a simultaneously presented word in the nonshadowed message. In both of these studies, there was essentially no recall of nonshadowed material at the end of the trials, indicating that the material had not entered LTM even though it was comprehended at some level. These findings, as well as the rapidly decreasing memory for nonshadowed material, may be handled by assuming that shadowing reduces rehearsal in a manner analogous to the role of counting in the Peterson and Peterson (1959) paradigm. It is commonly assumed that reducing rehearsal reduces LTM. On the other hand, rehearsal may not be needed for comprehension or STM—both of which appear to exist for nonshadowed material.

CONTEXTUAL CONSTRAINTS AND THE PERCEPTION OF SPEECH

STEVEN ROSENBERG[2]
Carnegie-Mellon University

WALLACE E. LAMBERT
McGill University, Montreal, Quebec

In the shadowing of connected discourse, *Ss'* performance deteriorated when intersentence relations were altered or disrupted. The following 3 methods were used to disrupt intersentence relations: (*a*) insertion of extraneous material, (*b*) permutation of sentence order, and (*c*) deletion of sentences. The insertion of extraneous material had the greatest effect on shadowing performance. This performance was most disrupted in the passages with the greatest number of anaphoric relations. At the shadowing lags found in the present study, *Ss* used intersentence relations as cues in their speech processing.

The present experiment investigated the effect of varying the contextual constraints between sentences on the shadowing of connected discourse. A shadowing task is of interest primarily because of the light it sheds on the mechanisms of immediate speech processing. Earlier researchers (Chistovitch, 1960; Chistovitch, Aliakrinskii, & Abul'ian, 1960; Galunov & Chistovitch, 1966) found that it was possible to shadow as closely as 200 msec. Consequently it was possible, when pressed, to shadow on the phonemic level, or, at most, the level of the word. In this case, the shadower does not use any other information beyond that in the immediate word or phoneme being processed. More recent experiments indicate that syntactic and semantic information from the whole sentence can be operative in shadowing. Using a series of statistical approximations, Treisman (1965b) found that *Ss* shadowed with less error as the material approached normal English. Using mixed sets, Miller and Isard (1963) found that normal sentences were better shadowed than nonsense sentences, which in turn were more easily shadowed than scrambled nonsense sentences. In our turn, we have shown how the relations between sentences can affect shadowing ability.

Olney and Londe (1966) and Olney (1969) investigated the class of intersentence relations called anaphoric relations, and specified criteria for tracing these relations between sentences. An anaphoric expression is one which functions in part as a substitute for a preceding expression in the same discourse. For example, in the following sentence, "It" is an anaphoric reference: "John hit the ball. It went over the fence." The number of anaphoric expressions in each test passage is a measure of the intersentence relations in that passage, although there are of course many other types as well. Two expressions were considered to be anaphorically related when they were coreferential. This class of intersentence relations is not exhaustive, but it does provide one quantitative measure of the contextual coherence of the 3 test passages, and is indicative of the relative amounts of intersentence relations in them.

Method. Three test passages were chosen which contained different amounts of intersentence connections. Passage I was a passage from an introductory textbook in psychology, Passage II was a newspaper editorial, and Passage III was a descriptive passage from a novel. Passage I had 40 anaphoric relations, Passage II had 21, and Passage III had 17 such relations.

To investigate the effects of the disruption of *contextual coherence* on shadowing ability, 8 levels of *contextual connectivity* (including the original unaltered passages) were established by systematically altering the 3 test passages. Four of these 8 levels are defined as follows: Level 1, original versions; Level 2, random-order sentences, in which each passage had the order of its sentences randomized, disrupting order- and contiguity-dependent intersentence relations; Level 3, reversed order of sentences, in which closeness of each sentence to the other was maintained so that, for example, word associations might still hold, but the sequence of order-dependent relations was altered; and Level 4, random sentences from the same source, in which new passages were formed by choosing, in each case, 22 sentences (without duplicating earlier choices) at random from the same source that provided the original passage; this preserves style, but little else.

The following manipulations, unlike the preceding ones, preserve the sentence order, but introduce extraneous material: In Level 5, alternation of passage sentences with samples from same source, a passage was chosen from the same source as the original and its sentences were alternated with the sentences from the original passage, in order, so that the first sentence from the first passage was followed by the first sentence from the second passage; then the second sentence from the first passage, and so on This intersperses the test passage with a second coherent passage in the same style. In Level 6, alternation of passage sentences with samples from other sources, sentences from Passage I were alternated with sentences from Passage III, likewise the sentences from Passages II and III, and from Passages I and II. This is similar to Level 5, except that now the interspersed

[1] This research was supported by subventions from the Canadian Defense Research Board and the Canada Council.
[2] Requests for reprints should be sent to Steven Rosenberg, Department of Psychology, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213.

passages differ on such things as style and a more divergent vocabulary. Level 7, alternation of partial passages from the same source, was identical to Level 5, except that every second sentence in each passage was deleted. Hence the first sentence of Passage I was followed by the second sentence of Passage II, and then by the third sentence of Passage I, etc. This reduces the coherence of the passage, which might have a greater effect on a passage such as I, which developed an argument, than on Passage III, which was descriptive. Level 8, alternation of partial passages from different sources, was identical to Level 6, except that, as in Level 7, every alternate sentence was deleted. Once again there are now style differences between the partially destroyed passages.

Passages I, II, and III each contained 22 sentences, although the number of words varied. Note that in each of the 8 conditions the test passage sentences have not been altered, only their relation to each other has been rearranged. Two practice passages about 6 min. in length were administered. These were literary in nature, but bore no relation through content or style to the test material.

The resulting 24 passages were recorded by a linguist at an average rate of 150 words/min, using normal inflection. Each *S* shadowed only one test passage, lasting 3–6 min. Five *S*s were tested on each passage, with the exception of the 3 original passages, where 11 *S*s per passage were used. A total of 138 *S*s participated. These *S*s were volunteers who had taken at least one psychology course, making them familiar with the "technical" terms in Passage I. They were tested in groups of approximately 12, in separate booths (with an empty booth between) of a language laboratory. All equipment was controlled by *E*, who also read the instructions aloud. The stimulus passage was given over headphones and also recorded on one track of a tape. The shadowed response was recorded on the other track.

Scoring. The raw data were scored for the number of errors per sentence. These results were transformed into percentages of words correctly shadowed per passage, permitting comparisons across passages. An error consisted of any response which differed, through omission, distortion, or substitution, from the original.

To score the time lag in shadowing, each of 2 scorers listened to a separate track containing either the test passage or the shadowed response. When the scorer listening to the stimulus track heard each fifteenth word, he pressed a relay to start an automatic timer. The second scorer also pressed a relay when hearing the same word on the track containing *S*'s response, stopping the timer. The timer gave an automatic printout of each time interval to the nearest millisecond, which was rounded off to the nearest tenth of a second. There were 30–60 time intervals measured per test passage.

Both error and time scores were taken only on those sentences from the original test passages.

TABLE 1

MEAN PERCENTAGE CORRECT (IN PARENTHESES) AND MEAN TIME SCORES (IN SEC.)

Contextual connectivity level	Passage I (Text)	Passage II (News)	Passage III (Novel)	*M*
1. Original version	(73.5) .681	(75.1) .498	(82.5) .517	(77.1) .565
2. Random order, within passage	(63.8) .792	(68.8) .515	(66.7) .668	(66.2) .659
3. Reversed order, within passage	(78.4) .690	(82.5) .509	(68.9) .529	(76.6) .576
4. Random, same source	(68.3) .564	(56.7) 1.114	(72.3) .611	(65.9) .763
5. Alternated, same source	(47.6) .832	(61.7) .643	(72.8) .544	(60.7) .673
6. Alternated, different source	(59.3) 1.074	(73.5) .742	(61.7) .758	(64.7) .858
7. Alternated and omitted, same source	(74.0) .762	(72.6) .576	(65.2) .651	(70.6) .663
8. Alternated and omitted, different source	(71.4) .769	(70.0) .588	(68.5) .673	(69.9) .677
M	(66.2) .770	(72.1) .648	(68.7) .619	

In conditions where other material was used to intersperse the sentences of the original passage, this interspersed material was not scored. Consequently some passages had a larger number of sentences scored than other passages. For example, in the last 2 conditions, sentences were deleted from the original passages. As there might have been a "ceiling" effect in the error scores, which were percentages, they were reanalyzed using an arc sine transformation (Winer, 1962, p. 221). These analyses did not differ significantly from those performed on the untransformed data. It is the analyses of the untransformed data that are reported below. The time latencies, on the other hand, had a lower, but no upper, limit, hence geometric means of each *S*'s scores were used in computing a mean time lag per *S* for a test passage. Nonhomogeneity of variance tests were not significant.

Results and discussion. Table 1 gives the mean percentage correct and mean time lag for the 3 original passages, and all manipulations of these passages. The 3 unaltered, original passages (Level 1) were tested for differences using a one-way analysis of variance. The analysis did not reveal significant differences in the ability of *S*s to shadow these passages.

Two separate analyses of variance (two-way) were performed on all 8 levels of the 3 test passages, on the error and time lag scores, respectively. There were significant passage differences for time lag scores, $F\ (2,\ 114) = 3.32$, $p < .05$. To investigate these passage differences, a one-way analysis of variance was performed on each test passage over all 8 levels of contextual connectivity. Passage I had significant variations in both error, $F\ (7,\ 38) = 3.96$, $p < .01$, and time scores, $F\ (7,\ 38) = 3.07$, $p < .05$, over all levels. Passage II had significant variations in time scores, $F\ (7,\ 38) = 3.79$, $p < .01$, over all manipulations. Passage III did not produce any significant differences.

To determine which manipulations were causing this effect, each level was compared to Level 1, the original versions. The comparison of Level 1 with Level 5 resulted in significant differences in error scores, t (47) = 2.22, $p < .05$. Similarly, the comparison of Level 1 with Level 6 resulted in significant differences in both error, t (47) = 2.24, $p < .05$, and time scores, t (47) = 3.05, $p < .01$. The results seem concentrated in the manipulations that preserve sentence order, but introduce an alternate context. To test this, a two-way analysis of variance was performed on Levels 1–3, which vary sentence order. No significant effects occurred. Similarly, Level 1 with Levels 5–8 were analyzed, and significant main effects for time and error differences between the levels resulted, Fs (4, 93) = 4.53 and 4.24, ps $< .01$, for the time and error scores, respectively. To test this, Level 1 was contrasted to Levels 5–8. This was significant for the error scores, F (1, 93) = 4.86, $p < .05$.

Our results show that in the shadowing of connected discourse, *S*s may use the relations between sentences. Along with earlier findings (Miller & Isard, 1963; Treisman, 1965a, 1965b) the authors have shown that *S*s are able to use contextual cues in shadowing. We have extended these previous findings that *S*s use relations within the sentence by showing that they are able to use the intersentence relations found in connected discourse as well.

Our manipulations of test passages reduced the ability of *S*s to shadow the *same* sentences in the various conditions. The insertion of sentences from an extraneous passage into the [illegible] assage caused most of the disruption in [illegible] mance. A larger effect was found in passag[illegible] n more anaphoric relations. No differences w[illegible] ound in the ability to shadow the unalter[illegible] ssages. Either the anaphoric relations do no[illegible] ct the shadowing of normal passages, or th[illegible] s differed on some other measure which [illegible] ces out any effect due to different numbers [illegible] aphoric relations.

CONDITIONS THAT DETERMINE EFFECTIVENESS OF PICTURE-MEDIATED PAIRED-ASSOCIATE LEARNING[1]

KEITH A. WOLLEN[2] AND DOUGLAS H. LOWRY[3]

Washington State University

Previous research has demonstrated that paired-associate learning is facilitated when the pairs are accompanied by pictures showing the pair members in some sort of spatial or interactive relationship. Two experiments extended the conditions under which such facilitation occurs. In Experiment I, facilitation was obtained even though all pictures were presented before any of the word pairs and no specific instructions were given to use the pictures. In Experiment II, interacting pictures produced facilitation relative to either a no-picture control or to controls having noninteracting pictures. Facilitation was obtained when the pictures were presented either before the word pairs or at the same time, but not when the pictures were presented after the pairs.

It is well known that *S*s can learn paired associates more rapidly when an interacting picture is shown along with each word pair than when no such picture is presented (e.g., Epstein, Rock, & Zuckerman, 1960; Wollen, Weber, & Lowry, 1972). A common interpretation of such facilitation is that the picture is stored with the word pair during input, and at output, the stimulus term presumably elicits an image of the interacting picture, which is then decoded into the response term (Paivio, 1971). In previous research on such matters, *S*s have been given the pictures at the same time as the words, and have been instructed to use the pictures to help them learn the pairs. The questions raised in Experiment I are: (*a*) just how effective are pictures when they are presented at a different time from the word pairs, and (*b*) whether pictures produce interference if they show 2 objects, only one of which is contained in the to-be-recalled pair.

EXPERIMENT I

Method. The learning materials consisted of the following pairs of concrete nouns: List 1—BOTTLE-HAMMER, KEG-TABLE, NAIL-FLOWER, SNAKE-ELEPHANT, WIGWAM-UMBRELLA, CHAIR-HOUSE, HORSE-TREE, WHALE-BIRD; and List 2—BOTTLE-KETTLE, KEG-APPLE, NAIL-LOBSTER, SNAKE-REVOLVER, WIGWAM-ARROW, CHAIR-FLAG, HORSE-FIRE, WHALE-DIAMOND. The 2 lists were counterbalanced such that half of the *S*s learned List 1 and half List 2. The words ranged from 6.23–6.90 on the imagery scale of Paivio, Yuille, and Madigan (1968). For each pair of words, a silhouette picture was made that depicted the 2 nouns in a spatial or interactive relationship (e.g., an arrow stuck in a wigwam, a hammer about to hit a bottle, etc.). Each silhouette and each word was made into a 2 × 2 in. slide. These materials were projected onto a 60-in. viewing screen.

The *S*s were 100 introductory psychology students whose participation partially fulfilled a course requirement. The *S*s were run in small squads of 5; these squads were randomly assigned to 5 experimental groups. As indicated in Table 1, the groups differed with respect to which of 4 different stages were used and which types of pictures were employed. In Stage 1, designated A–P_A, a word (the A term) was shown by itself for 1.5 sec. and was followed by a picture of that A term (P_A) presented by itself for 1.5 sec. This procedure continued until all eight A–P_A combinations had been presented. The *S*s were told to associate each word with the picture that followed it. Stage 2 consisted of the presentation of 8 pictures without any words. In each picture, 2 objects were depicted in a spatial or interactive manner. Depending upon the condition, the drawings pictured the 2 terms of the to-be-recalled pair (P_{A+B}) of Stage 3, the response term of the Stage 3 pair with an irrelevant object (C) (P_{C+B}), or the stimulus term of the Stage 3 pair with an irrelevant object (P_{A+C}). Each of these pictures was shown for 1.5 sec.; *S*s were told to pay close attention so that they could remember the pictures. Stage 3, designated A–B, involved the presentation of the stimulus word (A) of a pair for 1.5 sec., then the response word (B) for 1.5 sec., and finally a 1.5-sec. blank interval which served to separate the pairs. The *S*s were instructed to learn the pairs so that they could provide one member given the other; no mention was made of using the pictures from the previous stages. Finally, Stage 4 (test) consisted of presenting each A word for 1.5 sec. followed by a 3.5-sec. interval for *S* to write the missing B term.

Performance was expected to be the highest in Groups 1 and 2 since the objects pictured in Stage 2 were the same as those named in the A–B stage. In Groups 3 and 4, in contrast, the pictures might produce interference, as only 1 pair member (either A or B) was depicted in Stage 2. Group 5 represents a no-picture control.

Results. The mean numbers correct and numbers of overt errors are shown in Table 1. Since there were significant differences among the mean numbers

TABLE 1

Frequency Data in Experiment I

Group	Frequency	
	Correct responses	Errors
1 A–P_A, P_{A+B}, A–B, test	6.40	.65
2 —, P_{A+B}, A–B, test	6.05	.45
3 A–P_A, P_{C+B}, A–B, test	3.70	1.90
4 A–P_A, P_{A+C}, A–B, test	3.50	1.70
5 —, —, A–B, test	4.25	1.30

Note. Abbreviations: A = stimulus term, P = picture, B = response term, C = irrelevent object.

correct, F (4, 95) = 55.15, $p < .001$, a Dunnett's test was conducted comparing the Group 5 mean with each of the other 4 means. A difference of 1.23 was required at the .05 level. As expected, Groups 1 and 2 were significantly higher than Group 5. However, the trends for Groups 3 and 4 to score below the control group were not significant. The error data, which show the same trends, were not analyzed due to the small means and skewed distributions. In general, it appears that pictures can enhance performance even though they are presented at a different time from the word pairs.

Experiment II

In Experiment I, the superiority of Groups 1 and 2 might have been attributable to the fact that these groups in effect had 2 trials (P_{A+B} and A–B) whereas Group 5 had only 1 (A–B). This possibility was explored in Experiment II by giving the standard control group 2 successive trials (i.e., A–B, A–B) rather than 1. In addition, for every interacting-picture condition, there was another control group, which received pictures with the objects in a side-by-side, noninteracting fashion. The use of noninteracting pictures equated each interacting-picture group with its noninteracting control group in every respect except for the presence or absence of interaction; hence, interaction per se can be examined. Finally, groups were added in which pictures were presented (*a*) along with the word pairs, and (*b*) after all word pairs.

Method. The materials were the same as those used by Wollen et al. (1972) in their interacting–nonbizarre and noninteracting nonbizarre conditions. Basically, there were 9 high-imagery noun–noun pairs, each of which appeard at the bottom of a slide. When pictures were used, they appeared above the word pairs.

The design consisted of the 9 groups outlined in Table 2. The first and second columns indicate the conditions present on Trials 1 and 2, respectively. The symbols are the same as those used in Experiment I with the exception of P_{A-B} which refers to noninteracting pictures. For example, Group 2 received noninteracting pictures without words on Trial 1 and the word pairs al[illegible]rial 2; Group 6 received interacting pictures [illegible]anied by word pairs on both trials, and [illegible]ch group contained 20 introductory psych[illegible]dents (N=180) whose participation partially [illegible]d a course requirement. The *Ss* were [illegible]mall squads of 5 each. A randomized block [illegible]dure was used in which one squad was run [illegible] of the 9 conditions before beginning the next [illegible]

The sequence of events wa[illegible] Trial 1, 30-sec. interval, Study Trial 2, 50-se[illegible]l, Test Trial 1, 70-sec. interval, Test Trial 2 [illegible] pairs were presented in the same order on th[illegible]y trials and in 1 of 4 different orders on the 2 [illegible] The intervals between trials were used to pr[illegible]structions and to pick up and distribute re[illegible] sheets. Each slide, whether words only, pic[illegible] or both, was presented for 1.5 sec. with [illegible] on study trials. On test trial[illegible] were shown each stimulus word (or a[illegible]d naming one of the pictured objects) for 2 sec., f[illegible]wed by a 4-sec. blank period, during which *S* w[illegible] the missing response word (or object). All m[illegible] were presented via back projection to a 20[illegible]

The instructions varied some[illegible] according to condition. On Study 1, Group[illegible] 2 were told to study the pictures and to re[illegible]member as much about them as they could. Then on Study 2, these *Ss* were told to try to rememb[illegible] picture from Study 1 as an aid to Study 2 [illegible] they were also instructed to learn such that [illegible] could provide one member given the other. Groups 3, 4, and 5 were all told on Study 1 to l[illegible] so they could provide one member given th[illegible]ther. Group 5 received similar instructions for Study 2, but Groups 3 and 4 were instructed to study the pictures because the pictures would help them remember the previously presented word pairs. For both study trials, Groups 6 and 7 were told to use the pictures to help them learn the pairs. [illegible]ally, Groups 8 and 9 were instructed to learn the pictures so that they could name one object when given the name of the other. The instructions for test trials were simply to write the missing pair member.

Results and discussion. The mean number correct was determined for each test trial. Since there was

TABLE 2

Mean Correct in Experiment II

Group	Item		
	Study Trial 1	Study Trial 2	M correct
1	P_{A+B}	A–B	5.98
2	P_{A-B}	A–B	4.58
3	A–B	P_{A+B}	5.40
4	A–B	P_{A-B}	5.65
5	A–B	A–B	4.18
6	A–B P_{A+B}	A–B P_{A+B}	6.72
7	A–B P_{A-B}	A–B P_{A-B}	5.32
8	P_{A+B}	P_{A+B}	6.10
9	P_{A-B}	P_{A-B}	4.88

Note. Abbreviations: P = picture, A = stimulus term, B = response term; P_{A-B} indicates a noninteracting picture and P_{A+B} indicates an interacting picture.

Means are for combined data for the 2 test trials.

relatively little difference between the 2 trials, Table 2 presents only the means of the 2 test trial means. A simple randomized analysis of variance on all 9 groups was significant, F (8, 171) = 3.23, $p < .01$. Consequently, each group was compared to the standard control (Group 5) using Dunnett's test. The difference required for significance at the .05 level (1.51) was only reached by those groups having interacting pictures on Study 1 (Groups 1, 6, and 8). As expected, having interacting pictures only on the second study trial (Group 3) failed to produce a significant amount of facilitation. Similarly, none of the conditions with noninteracting pictures produced a significant amount of facilitation.

In addition to the above analyses, 1-tailed t tests were run comparing each group having interacting pictures with its noninteracting-picture control. Group 1 was higher than Group 2, t (38) = 1.86, Group 6 was above Group 7, t (38) = 2.43, and Group 8 was above Group 9, t (38) = 2.37, all $ps < .05$. However, Group 3 was not above Group 4; in fact, Group 3 was slightly inferior. Hence, the same results emerge as when each group was compared with Group 5; namely, interacting pictures facilitate when pictures are presented on Study 1 (Groups 1, 6, and 8) but not when they appear only on Study 2 (as in Group 3).

Together, Experiments I and II indicate that interacting pictures produce a higher level of response than noninteracting pictures, or than no pictures at all. This facilitation occurs when (*a*) the pictures and word pairs are presented simultaneously or (*b*) all of the pictures are presented before any of the words, but not when (*c*) the pictures are given only after the presentation of the word pairs.

ROLE OF DETAILS IN THE LONG-TERM RECOGNITION OF PICTURES AND VERBAL DESCRIPTIONS[1]

THOMAS O. NELSON[2]
University of Washington

JACQUELINE METZLER
Stanford University

DAVID A. REED
University of Washington

University undergraduates studied and then had immediate and delayed recognition tests on either (*a*) photographs, (*b*) verbal descriptions of the main theme of the photographs, (*c*) unembellished line drawings of the main theme of the photographs, or (*d*) main-theme line drawings embellished with extra details from the photographs. Although the 3 pictorial conditions had higher recognition than the verbal condition, they did not differ from each other on either the immediate or delayed recognition tests. These results imply that the recognition advantage for pictures over verbal descriptions is not due to the extra details which pictures contain.

It is well known that immediate recognition is very high for ordinary pictures (Nickerson, 1965; Shepard, 1967). Furthermore, immediate recognition is nearly always higher for pictures than for verbal descriptions (but see Goldstein, Locke, & Fehr, 1972). It has also been established that *long-term* recognition is quite high for pictures (Nickerson, 1968; Shepard, 1967). Although the long-term recognition of pictures has not been directly compared with that of verbal descriptions, the results of studies examining long-term recognition of verbal descriptions only (e.g., Strong, 1913) suggest that long-term recognition might be higher for pictures than for verbal descriptions. Such a direct comparison in long-term recognition of pictures vs. verbal descriptions was one focus of the present study.

Because of the myriad of details contained in ordinary pictures, the verbal descriptions of most pictures are not entirely complete (cf. the aphorism "a picture is worth a thousand words"). One might explain any recognition advantage for pictures over verbal descriptions in terms of the extra details contained in the pictures but not in the verbal descriptions; if *S* encodes additional pictorial details during study, then recognition of any one of those details at the time of test could serve as the basis for distinguishing the target picture from the distractor. These extra details, collectively referred to here as "embellishment," have been considered by previous researchers (Haber, 1970; Nickerson, 1965) as a possible determinant of the high recognition accuracy for pictures. The second (and major) focus of the present study was to directly manipulate the number of details contained in the to-be-recognized pictures to determine if extra pictorial details facilitate recognition.

Method. There were 4 sets of stimuli, each containing 120 items. One set (PH) consisted of black-and-white photographs used in a previous experiment (Nickerson, 1965).[3] Two student judges independently examined the photographs and generated a one-sentence description of each photograph. The few differences that occurred in the 2 judges' descriptions were reconciled by a third student judge. The final 120 verbal descriptions (VD) comprised the second stimulus set. Line drawings of the photographs were constructed on the basis of the PH and VD stimulus sets, so as to include only those aspects of the photograph that were mentioned in the verbal description. The resulting line drawings comprised the third stimulus set, unembellished line drawings (ULD). Finally, extra details from the PH stimuli were added to ULD to form the fourth stimulus set, embellished line drawings (ELD). It should be noted that ELD was not as detailed as PH, since the latter contained shading and fine-grain details that could not be included in a line drawing. An example of an item appearing in each of the 4 conditions (VD, ULD, ELD, and PH) is shown in Figure 1.

The *Ss*, run in groups of 4–5, were 136 undergraduates at the University of Washington, whose participation fulfilled a course requirement. One independent variable (between-*Ss*) concerned the type of to-be-recognized items. The *Ss* were assigned to conditions according to order of appearance, beginning with 34 *Ss* per condition, and complete data were obtained from 33 *Ss* in Condition PH, 34 *Ss* in ELD, 30 *Ss* in ULD, and 31 *Ss* in VD (the loss of data from 8 *Ss* was due to failure to return for the second session). The second independent variable (within-*Ss*) was the retention interval for the recognition test, which was either immediate (7 min. after the items had been studied) or delayed (7 wk. after the items had been studied). Both tests were 2-alternative forced-choice recognition tests. To avoid the problem of having once-

[1] This research was begun while T. O. Nelson was a National Science Foundation Postdoctoral Fellow at Stanford University, 1970–71, and was completed with the support of U.S. Public Health Service Grant MH-21037 to T. O. Nelson. The authors thank David Gorchoff for his help in pilot research, Colin MacLeod and Karen Woodbury for assisting in the statistical analysis, and Geoffrey Loftus for his comments on the manuscript.

tested items in the immediate test and twice-tested items in the delayed test, the following technique was used. Of the 120 items in a given condition, 60 were studied and 60 served as distractors. Thirty of the 60 studied items were tested only on the immediate test, whereas the remaining 30 studied items were tested only on the delayed test; similarly, 30 of the 60 nonstudied items were the immediate-test distractors, whereas the remaining 30 nonstudied items were the delayed-test distractors. Items were counterbalanced across *S*s so that a given item served approximately equally often in each of the 4 studied–nonstudied immediate–delayed conditions.

During study, a Kodak Carousel projector presented the items at a rate of 10 sec. per item. Following presentation of the last study item, *S* solved arithmetic problems for 7 min. while *E* rearranged the slide trays for the immediate recognition test. During the recognition test, pairs of test items were presented simultaneously from 2 Kodak Carousel projectors, synchronized by an external timing device to present each pair of test items for 15 sec. The *S* made a written response to indicate whether the previously studied item was the left or right member of the test pair, guessing whenever necessary. Half of the previously studied items were on the left and half were on the right, intermixed according to a Gellerman sequence (1933). Seven weeks later, *S* returned for the delayed recognition test. The 30 test pairs were presented at a rate of 20 sec. per pair, and *S* made a written response to indicate which member of the pair he had previously studied, guessing whenever necessary.

Results. The mean percentage of correct recognitions for each condition of the immediate and delayed tests is shown in Figure 2. These data were analyzed by a 4 × 2 (Conditions × Retention Interval) mixed-model analysis of variance. Recognition accuracy was significantly higher on the immediate test than on the delayed test, F (1, 124) = 284.5, $p < .001$. The main effect of the 4 conditions was also significant, F (3, 124) = 13.3, $p < .001$, but only because PH, ELD, and ULD were significantly higher than VD (PH, ELD, and ULD were not significantly different from each other, $p > .05$). The Conditions × Retention Interval interaction was also significant, F (3, 124) = 10.5, $p < .001$; analyses of the simple interaction effects showed that recognition accuracy declined over the retention interval significantly more slowly for PH, ELD, and ULD than for VD (the rates of decline for the former 3 conditions did not differ significantly, $p > .05$). Parenthetically, it should be noted that, except for a significant simple interaction effect of ELD–ULD × Retention Interval ($.025 < p < .05$), transformation of the percentage correct data to d' did not alter any of the above findings.

Discussion. Not only were immediate recognition and long-term recognition better for the pictorial conditions than for the VD condition, but the rate of recognition loss over the retention interval was

"A SMILING OLD MAN HOLDS A LITTLE GIRL"

FIGURE 1. Example of an item in each of the 4 conditions (from top to bottom: verbal description, unembellished line drawing, embellished line drawing, and photograph).

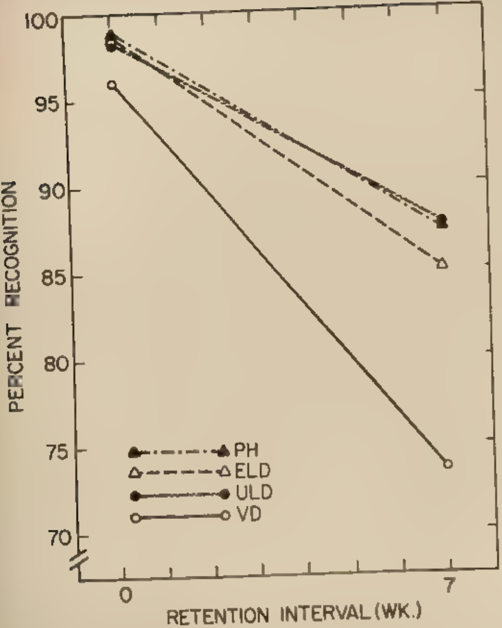

FIGURE 2. Mean percentage of correct recognitions as a function of retention interval. (Curve parameter is condition: photograph—PH, embellished line drawing—ELD, unembellished line drawing—ULD, and verbal description—VD.)

greater for VD than for the pictorial conditions. Theoretical interpretations of the latter finding in terms of forgetting should be made with caution because the high degree of original learning may or may not have been the same for the VD and pictorial conditions; however, if one is interested in the practical consequences of presenting various informational representations (verbal, pictorial) for the same amount of study time, then long-term recognition is shown to be higher for pictorial representations than for verbal representations.

The lack of effect of embellishment on pictorial recognition was quite unexpected. If the superior recognition of pictures is due to the extra details that pictures typically contain, then recognition accuracy should have occurred in the order PH > ELD > ULD. The absence of this ordering does not mean that unusual details never facilitate picture recognition, but rather that the commonplace details found in ordinary pictures do not seem to be a determinant of the superior recognition for those pictures. The theoretical problem is accounting for the lack of a facilitative effect of details while at the same time accounting for the fact (Loftus, 1972, p. 537; Poetzl, 1917) that pictorial details are entered into the information-processing system. One hypothesis that could account for both sets of findings has to do with *conservation* of processing. Suppose that for a fixed amount of processing time, *S* stores a constant amount of information about a picture, regardless of the number of details contained in the picture. That is, if one picture contains relatively few details, then *S* will store a relatively large amount of information about each detail; if another picture contains relatively many details, then *S* will store a relatively small amount of information about each detail. Because the *total* amount of stored information is the same for the 2 pictures, subsequent recognition performance would not be affected by the number of extra details (even though the extra details are stored in memory). Although this conservation hypothesis can account for the present findings about PH, ELD, and ULD, an explanation is still needed to account for the recognition advantage of pictures over verbal descriptions. The present study serves only to disconfirm the notion that this recognition advantage is due to the extra details which pictures typically contain.

American Psychological Association

Vol. 102, No. 2 February 1974

The *Journal of Experimental Psychology* publishes original experimental investigations which are judged by the Editors to contribute substantially and significantly toward the development of psychology as an experimental science. Studies with normal human subjects are favored over studies involving abnormal or animal subjects, except when the latter are specifically oriented toward the extension of general psychological theory. Experimental psychometric studies and studies in applied experimental psychology or engineering psychology may be accepted if they have broad implications for experimental and theoretical psychology.

Manuscripts. Submit manuscripts in *duplicate* to the Editor: David A. Grant, Department of Psychology, University of Wisconsin, Psychology Building, Charter and West Johnson, Madison, Wisconsin 53706. Manuscripts must be accompanied by an abstract of 100 to 150 words *typed on a separate sheet of paper.* The abstract should conform to the style of *Psychological Abstracts.* Detailed instructions for preparation of the abstracts appear in the *APA Publication Manual,* pp. 11–12.

The Journal offers its authors the option of a "blind" review of their submitted manuscripts under the conditions described in the Special Announcement (1972, Vol. 94, No. 3, p. 325). If the author wishes to have his identity hidden from the reviewer, he should request a blind review and take sole responsibility for preparing his manuscript in such a way as to hide his identity.

Manuscripts *must* adhere to the conventions concerning reference citations, preparation of tables and figures, manuscript format, etc., as described in the 1967 revision of the *Publication Manual* of the American Psychological Association. When in doubt about practices of the Journal, authors should examine a recent issue.

Clear, concise exposition is demanded; verbose manuscripts may be returned for revision before being reviewed. Piecemeal experiment-by-experiment reporting is discouraged, and integrated series experiments executed simultaneously (e.g., most doctoral dissertations) *must* be reported in a single paper. Regular papers cannot exceed 20 printed pages. Simple experiments, replications, and supplementary experiments may be published as Short Reports of not more than three printed pages. Reports of negative results and failures to replicate published work are also acceptable if they stand on their own merits as contributions to knowledge.

Normally papers are published in order of their receipt, and the current publication lag is about ten months. All of the cost of an author's alterations in galley proof is charged to the author.

Most of the editorial decisions on manuscripts submitted to the Journal are made by the Editor or one of the Associate Editors. In addition, although listed on the Masthead as Consulting Editors, Norman H. Anderson, Helen Bohmer Daly, Murray Glanzer, and Judith Goggin serve as Special Action Editors. As such, they make the editorial decisions on a limited number of manuscripts rather than serve as reviewers for the editors.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1974: $60 domestic, $61 foreign, $6 single issue. APA member rate: $25. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive galley proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., 175 Fifth Avenue, New York, New York 10010; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. Undelivered copies resulting from address changes will not be replaced; second-class mail is not forwarded unless subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published monthly in two volumes, six issues per volume, by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and additional mailing offices.

LOCUS OF CONTROL AND LEARNED HELPLESSNESS [1]

DONALD S. HIROTO [2]

University of Portland

Failure to escape, the defining characteristic of learned helplessness, was investigated with perceived and instructed locus of control *S*s in a learned-helplessness paradigm. Three groups, equally divided between internals and externals and counterbalanced for sex, received different treatments with an aversive tone prior to the testing for helplessness. The first group could neither escape nor avoid an aversive tone, the second group could escape the tone, and the third group was not exposed to the treatment. Eighteen escape–avoidance trials followed, using a human analogue to an animal shuttle box, in which *S*s received an instructional set describing the task as skill or chance determined. In addition to a complete replication of learned helplessness in man, externals were significantly more helpless than internals, and chance-set *S*s were more helpless than skill-set *S*s. Since uncontrollability of noise, externality, and chance instructional set all impaired escape–avoidance in parallel ways, it was speculated that a common state may underlie all 3 dimensions—expectancy that responding and reinforcement are independent.

Overmier and Seligman (1967) and Seligman and Maier (1967) demonstrated a profound interference with shuttle box escape–avoidance behavior of dogs given prior inescapable electric shock. They hypothesized that dogs given inescapable shock failed to escape later because they had learned that shock termination was independent of responding. This learning was hypothesized to interfere with later acquisition of escape because the incentive for initiating responses had been lowered, and the ability to associate responding and shock had been proactively impaired. "Learned helplessness" was chosen as the descriptive label for the phenomenon and also as the hypothesized process by which learning of independence between responding and reinforcement interferes with future responding.

A social-learning construct, internal–external control of reinforcement (Lefcourt, 1966; Rotter, 1966), seems conceptually similar to the hypothesized learned-helplessness process. The internal–external locus of control refers to the degree to which an individual perceives that reinforcements are contingent on his actions. An "internal" tends to perceive reinforcement as a consequence of his responses and to attribute the reinforcement contingencies to his skills and abilities; an "external" tends to perceive reinforcements as un-

[1] This article is based on a dissertation submitted to the University of Portland in partial fulfillment of the requirements for the PhD degree. The author thanks the dissertation chairman, William H. James, and the members of the committee, John R. Donoghue, George S. Larimer, B. Kent Parker, and Philip Van Bruggen. Special acknowledgments go to Martin E. P. Seligman for his comments and suggestions in the preparation of this report.

related, i.e., independent of his behavior, and to attribute outcomes to luck, chance, or another person.

Learned helplessness and the internal–external construct both view control of reinforcement as a crucial variable. Maier, Seligman, and Solomon (1969) and Seligman, Maier, and Solomon (1971) emphasized 2 consequences of uncontrollable events on later learning: dogs, cats, mice, goldfish, and probably rats are (*a*) slower to initiate responses to escape, and (*b*) retarded at learning that responding controls trauma. Reviews of the literature on the internal–external construct (Joe, 1971; Lefcourt, 1966, 1972; Rotter, 1966) report that external *S*s are slower than internal *S*s in learning a variety of tasks. Apparently, lack of control over reinforcement, whether real or perceived, impairs a variety of species on a variety of tasks.

A major purpose of the present study was to investigate learned helplessness in internal and external *S*s. It was predicted that *S*s given inescapable/unavoidable pretreatments would show retarded acquisition and performance measures relative to *S*s without such pretreatments, and that such retardation might be a function of externality. Previous studies with dogs as well as humans (Racinskas, 1971; Thornton & Jacobs, 1971) used electric shock as the aversive stimulus. The present study used a loud tone rather than shock as the aversive stimulus in an attempt to extend the generality of learned helplessness to a new noxious event (see also Braud, Wepmann, & Russo, 1969).

The concept of control is central to both helplessness and internal–external studies, but the definitions of the term differ. In helplessness, control refers to *E* actually arranging the events as independent of responding; while internal–external construct studies refer to perceptions of the actual events. In view of the differing reference bases of control, we introduced an instructional set to determine if perceptual set interacted with helplessness. It was predicted that *S*s pretreated with inescapable noise and then given escape–avoidance trials under an instructional set of chance would be more helpless than und[illegible]kill instructions. This parallels our pre[illegible]tion that externals would be more help[illegible]an internals following inescapable noi[illegible]

METHOD

Subjects. All *S*s were introductory [illegible]logy students at the University of Portland [illegible] administered the Internal–External form [illegible]'s Dekalb Survey Tests: Student Opinion S[illegible]y at least 8 wk. prior to the study. The Jame[illegible]ale is based on the early work of Rotter (1954) a[illegible]hares (1955) and provides a measure of the [illegible]nt to which *S* perceives reinforcements as being co[illegible]ngent on his actions or as resulting from externa[illegible]ctors. The scale is a Likert-type instrument w[illegible]4 response choices for each of the 30 critica[illegible]d 30 filler items.

A total of 96 *S*s with internal–external [illegible]res at least 1 *SD* above or below the mean were r[illegible]omly assigned to 1 of the 3 treatment groups and [illegible]of the 2 instructional-set groups, with each cell [illegible]nterbalanced for sex and locus of control.

Apparatus. Two distinctively differe[illegible] units were located on different tables. The a[illegible]ratus in the pretreatment was a red spring-loade[illegible]utton housed in a 1-in.-sq. wooden base. In the [illegible]scape condition the button was connected to rel[illegible]s controlling the termination of the aversive st[illegible]mulus, while in the inescapable condition the but[illegible]n was independent of the aversive-stimulus term[illegible]tion.

The apparatus in the phase testing for help[illegible]ness was a modified Manipulandum Type S task originally designed by Turner and Solomon (1962) as a human analogue to the 2-way shuttle box used in animal learned-helplessness studies. The manipulandum was 24 × 5 × 6 in., with a 3-in. knob protruding from the top. The knob slid on a 19 × ½ in. straight channel on the cover of the box. Attached to the knob on the underside of the channel was a 2½-in. wooden disk. The escape–avoidance response was sliding the knob to either side of the manipulandum so that the wooden disk made contact with a hidden microswitch. Only 1 of the microswitches on any trial would terminate the stimulus, so that on the next trial, the alternate switch would terminate the stimulus.

The aversive stimulus was a 3,000-Hz. tone pretaped on a Sony tape recorder and presented to *S* through North American earphones. A Beltone 15-C Audiometer recently calibrated to standards set by the International Organization for Standardization measured the stimulus at 110 db. All response variables were measured by standard (1/100-sec.) timers and counters located in an adjacent room separated by a 1-way mirror.

Procedure. Each *S* was escorted into the experimental room and informed that the study involved listening to "some loud noise which has been judged to be somewhat unpleasant but not harmful or dangerous to you." A 3-sec. sample of the 3,000-

Hz. tone was first presented, then each S was assigned to 1 of the 12 cells from the $3 \times 2 \times 2$ (Treatments $\times$ Instructional Sets $\times$ Locus of Control) factorial combination.

The treatment groups included (*a*) escape (E) *S*s, who received unavoidable/escapable pretreatments, (*b*) inescapable ($\bar{E}$) *S*s, who received unavoidable/inescapable pretreatments, and (*c*) no-pretreatment (NP) *S*s who received only the test trials with the manipulandum.

Tape-recorded instructions for pretreated *S*s were an expanded and modified version which Turner and Solomon (1962) described as adequate:

> Listen to these instructions carefully. I am not allowed to give you additional information other than what is given to you now. So please listen and do not ask me any questions. From time to time a loud tone will appear. When that tone comes on, there is something you can do to stop it.

The pretreatments consisted of 30 unsignaled 5-sec. trials with the 3,000-Hz. tone. The intertrial interval (ITI) ranged 15–25 sec., with a 20-sec. mean ITI. At the conclusion of the pretreatments, S rated the aversiveness of the auditory stimulus.

The testing for helplessness was conducted with the shuttle box manipulandum at a different table but within the same experimental room. The NP *S*s were given the preexperimental instructions and a 3-sec. sample of the tone prior to being seated at the table. The manipulandum was covered until S received 1 of the 2 instructional sets describing the task. The first half of the taped instructions was identical and were presented to all *S*s:

> You will be given some trials in which a relatively loud tone will be presented to you at different intervals. Now here is the important part, and I want you to listen carefully. Whenever you hear the tone come on there is something you can do to stop it.

The second half of the instructions varied according to the particular set. The "skill" instructions emphasized direct control over the 3,000-Hz. tone:

> What you do is really up to you to figure out. There is a solution to the problem, and if you figure it out the tone will stop. Therefore, the amount of unpleasantness you receive is dependent on your skills and abilities to find the solution to the problem. You are potentially in control of the situation.

The "chance" instructions emphasized that S had no direct control over the stimulus and that chance factors predicted success:

> But I will be controlling the solution to the problem. In other words, the way to stop the tone is really up to me. As far as you are concerned this is a guessing game. When you guess correctly, the tone will automatically stop. But if your guess is wrong the tone stays on.

After the instructions, S uncovered the manipulandum. The knob was always located at the midpoint of the manipulandum, so that S could slide the knob equidistant to either the left or right end of the box. The test phase consisted of 18 signaled 10-sec. trials. A 5-sec. red light, located at the midpoint of the manipulandum cover, preceded the onset of the 5-sec. auditory stimulus, with the offset of the light coinciding with the onset of the 3,000-Hz. tone. The ITI ranged 20–55 sec., with a mean ITI of 20 sec.

The appropriate response was moving the knob to one side of the manipulandum on one trial and sliding the knob to the opposite side on the next trial. An avoidance response was terminating the red light prior to the onset of the auditory stimulus, i.e., a response latency of 5 sec. or less, while an escape response was terminating the tone between 5 and 10 sec. after trial onset. If S did not terminate the light or noise, a latency of 10 sec. for that trial was recorded. At the completion of the test phase, S was asked to rate the unpleasantness of the tone, paid \$2, and debriefed.

Five response measures were used during the test: (*a*) trials to criterion for avoidance acquisition, defined as 3 consecutive avoidance responses; (*b*) trials to criterion for escape acquisition, defined as 3 consecutive escapes; (*c*) number of avoidance responses for the 18 trials; (*d*) number of failures to escape, defined as number of trials with a latency of 10 sec.; and (*e*) the overall mean response latency for the 18 trials. These indices, particularly *c*, *d*, and *e* parallel the indices reported in the animal helplessness literature.

RESULTS

Animal learned helplessness was characterized by the similarity in escape–avoidance behavior between E and NP *S*s, while $\bar{E}$ *S*s revealed longer response latencies and more failures to escape than either of the other *S*s. The results of this experiment disclosed remarkable similarities to the animal studies. The $\bar{E}$ group was retarded in escape–avoidance measures relative to the E and NP groups, with the latter groups not differing from each other.

Maier et al. (1969) reported that approximately 63% of $\bar{E}$ dogs and about 5% of naive dogs failed to escape in the shuttle box. Human *S*s demonstrated similar but somewhat less dramatic findings. On the average, $\bar{E}$ *S*s failed to escape the aversive stimulus on over 50% of the 18 trials, while E *S*s failed on 13% and NP *S*s failed on 11% of the trials. Approximately 34% of the $\bar{E}$ *S*s failed to reach criterion, com-

pared to 8% of the E and NP Ss who also failed to reach criterion. Figure 1 presents the response latencies of the 3 treatment groups on the 6 blocks of 3 trials. The horizontal line at the 5-sec. mark on the ordinate represents the boundary between escape and avoidance: Points plotted above the 5-sec. line represent escapes, while points below the line denote avoidance responses. The $\bar{\text{E}}$ group shows consistently longer latencies than either the E or NP groups, with the latter groups performing near equality.

An analysis of variance (ANOVA) test on response latency found a main effect of treatment, F (2, 84) = 12.38, $p < .01$, and a Treatments × Trial Blocks interaction, F (10, 420) = 2.29, $p < .05$. Two planned orthogonal comparisons between groups indicated that the main effect was due to the variability of $\bar{\text{E}}$ Ss. The first comparison between $\bar{\text{E}}$ vs. the average of E and NP Ss was significant ($p < .01$), while the second comparison found no differences between E and NP Ss. A simple main effects analysis on the Treatments × Blocks interaction disclosed significant differences between groups at each of the 6 trial blocks ($p < .02$). Scheffé S tests revealed that $\bar{\text{E}}$ Ss had consistently longer latencies at each of the trial blocks than either E or NP Ss, while the latter Ss did not differ from each other.

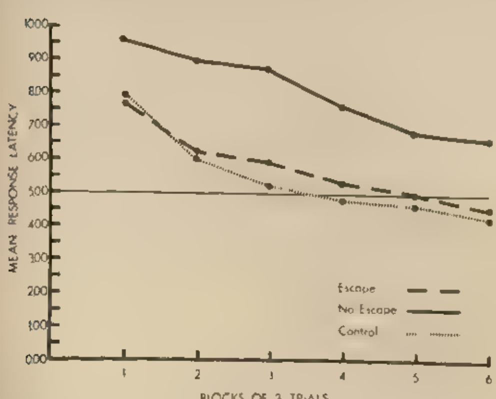

FIGURE 1. Mean response latencies of the 6 escape–avoidance trial blocks for the 3 treatment groups.

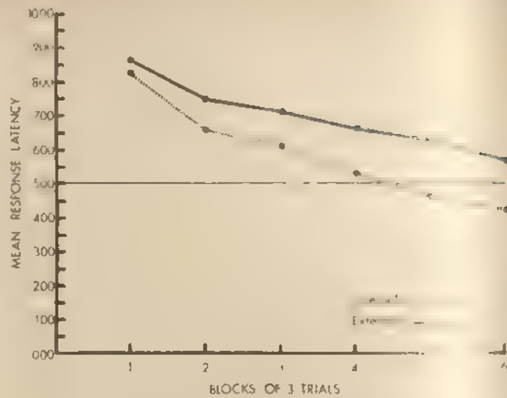

FIGURE 2. Mean response latencies of the 6 escape–avoidance trial blocks for internal and external control Ss collapsed over the 2 experimental factors.

A treatments main effect was found with the failure to escape measure, F (2, 84) = 22.57, $p < .01$, and trials to criterion for escape acquisition,[3] F (2, 66) = 1[illegible].49, $p < .01$. A planned orthogonal comparison indicated that these main effects were due to differences between E Ss and the average of E and NP Ss ($p < .01$). This planned comparison also found a significant effect on the trials to criterion for avoidance acquisition: $\bar{\text{E}}$ Ss took longer to reach acquisition than the average of E and NP Ss, F (1, 84) = 4.45, $p < .05$. The second orthogonal comparison found no differences between E and NP Ss on any of the 4 dependent measures.

Other factors, independent of treatment, were also significant. External locus of control Ss, regardless of their pretreatments and instructional sets, were slower to escape or avoid than internal control Ss. Figure 2 presents the response latencies of the internal–external factor on the 6 trial blocks. An ANOVA on response latencies disclosed an internal–external main effect, F (1, 84) = 6.58, $p < .05$, and a Trial Blocks × Internal–External interaction, F (5, 420) = 3.24, $p < .05$.

[3] Analysis of the escape-acquisition measure was based on unequal ns as some Ss (18) reached avoidance criterion without first reaching escape criterion. There was no statistical relationship between the 18 Ss dropped from the analysis and any of the experimental treatment factors.

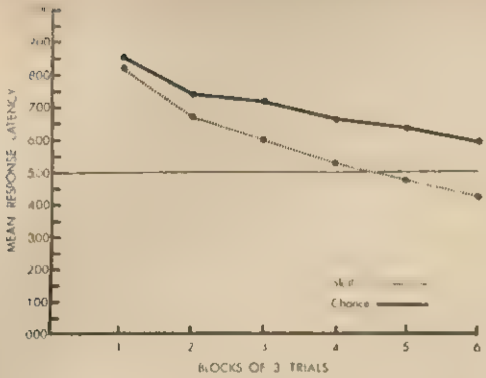

FIGURE 3. Mean response latencies of the 6 escape–avoidance trial blocks for the instructional-set *S*s collapsed over the 2 experimental factors.

A test for simple main effects on the interaction revealed that external control *S*s responded slower than internal control *S*s on Trial Blocks 4, 5, and 6 ($p < .025$). External *S*s also required more trials to reach avoidance criterion ($M = 18.3$) and made fewer avoidance responses during the 18 trials ($M = 3.1$) than internal *S*s (*M*s = 15.0 and 6.2, respectively). The ANOVA tests on these measures statistically verified the observed differences ($p < .05$). There were no internal–external differences for the escape-acquisition or failures-to-escape measures.

The chance-set group displayed retarded measures compared with the skill-set group. Figure 3 presents the response latencies of the instructional set factor collapsed over the 2 experimental factors. The ANOVA found a main effect of instructions, $F(1, 84) = 5.93$, $p < .05$, and a Trial Blocks × Instructions interaction, $F(5, 420) = 4.28$, $p < .05$. A simple main effects analysis indicated that chance-set *S*s had longer latencies than skill-set *S*s on Trial Blocks 4, 5, and 6 ($p < .025$). The effects of instructional set also interfered with avoidance responding. Compared to skill-set *S*s, chance-set *S*s required more trials to reach avoidance criterion (*M*s = 18.2 and 15.1, respectively) and made fewer avoidance responses (*M*s = 3.2 and 6.1, respectively). The ANOVAs computed on these measures were all significant ($p < .05$). There was no effect of instructions on either the escape-acquisition or failures-to-escape measure.

The results of internal vs. external and instructional set indicate that either factor can produce parallel results of inescapability. That is, inescapability, chance set, and externality retard escape–avoidance behavior.

Interestingly $\bar{E}$ internal *S*s made more button presses i.e., escape attempts, in pretreatment than $\bar{E}$ external *S*s (*Mdn*s = 21 and 5.5, respectively), $\chi^2 = 3.97$, $p < .05$, suggesting that persistence in trying to control an uncontrollable event may be correlated with the absence of later helplessness. This is similar to Seligman and Maier's (1967) concept of immunization where dogs with prior escapable shock demonstrated enhanced panel pressing under inescapable shock and were later not helpless.

There were no significant interactions between the experimental factors on any response measure. However, a priori comparisons permitted an analysis of possible interaction within the E group. Figure 4 presents the mean latencies of internal and external $\bar{E}$ *S*s across the 6 trial blocks. The *F* test for planned orthogonal comparisons revealed that the overall mean latency of externals was statistically longer than that of internals, $F(1, 84) = 5.46$, $p < .05$. No other dependent measure approached significance. Inescapability and instructional set were

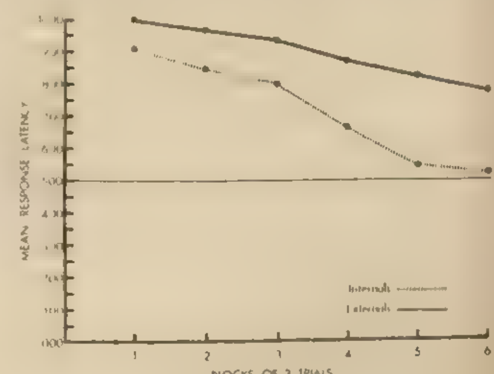

FIGURE 4. Mean response latencies of internal and external control *S*s in the inescapable treatment group for the 6 escape–avoidance trial blocks.

analyzed next. Dunn's test for planned nonorthogonal comparisons was not significant with any of the 5 response measures.

Further analysis was conducted on a possible confounding variable. There was no yoking procedure in the pretreatment, so that duration of noise exposure was not equated. The Ē group received 5 sec. of aversive noise on each trial, whereas the E group received an average of 1.4 sec. of noise per trial. Since Ē Ss received longer periods of the loud tone, and perhaps greater stress, it could be argued that differential stress rather than uncontrollability led to the retarded performance with the shuttle box manipulandum. However, *S* ratings of the noise did not reveal significant differences: the Ē group rated the 110-db. tone at 3.55 on a 7-point scale, while E group rated the same tone at 3.66. This difference was not statistically different and suggests that differential stress did not produce the helplessness effects. It should also be noted that the relatively moderate ratings of the 110-db. stimulus indicates that learned helplessness can be produced with moderately aversive events as well as the more traumatic events used in the animal studies.

Discussion

Learned helplessness can be experimentally produced in man. Both animals and man show longer latencies and more failures to escape following inescapable aversive events than following escapable events or no pretreatment. The inescapable pretreatments did not affect the total number of avoidance responses between groups (see also Seligman & Maier, 1967). It should be noted that Overmier (1968) reported interference with avoidance acquisition when escape contingencies were eliminated in the shuttle box. Considering the divergent findings, perhaps it is only initial learning—escape or avoidance, whichever occurs first—that is disrupted by inescapability.

The first published account of learned helplessness in humans (Thornton & Jacobs, 1971) had 2 methodological problems. First, an instructional set was confounded with inescapability in the pretreatment. The Ē *Ss* received instructions that described the noncontingency between shock and responding, and E *Ss* received different instructions that described the contingency between shock and avoidance. These different instructions, embedded within the different pretreatments, may have predetermined *Ss*' responses to [illegible] a relationship in the study. The second problem relates to the unusual pretreatment procedures. Previous animal helplessness studies pretreated Ē *Ss* with unavoidable-inescapable shock. Thornton and Jacobs, however, pretreated their Ē *Ss* with avoidable-escapable shock. Because of the different procedures, their study cannot be considered an analogue to the helplessness studies. Thornton and Jacobs, rather than demonstrating learned helplessness, demonstrated the effect of prior avoidance training on a later escape-avoidance task.

The learned-helplessness hypothesis identifies control over reinforcement as the crucial variable. The present study confirmed the hypothesis by demonstrating that Ē Ss produced greater impairment in escape-avoidance than E or NP *Ss*. In addition, the external locus of control variable, also concerned with control of reinforcement, interacted with inescapability to produce greater impairment than internal control *Ss*.

In conclusion, this study demonstrated that helplessness can be experimentally induced in man wholly parallel to helplessness in animals. The *S* variable of externality appears to function like the pretreatment variable of inescapability, as evidenced by the interaction between externality and the helplessness induction. Both locus of control and skill-chance instructional set factors produced an effect similar to inescapability. In view of the parallel effects between the 3 factors, I suggest that a single process may underlie learned helplessness, externality, and the perceptual set of chance—the expectancy that responding and reinforcement are independent. Seligman (in press) and Miller and Seligman (1973) have pointed to this cognition as the underlying state in reactive depression in man.

CONDITIONED ADAPTATION TO PRISMATIC DISPLACEMENT: TRAINING TRIALS AND DECAY[1]

JEROME H. KRAVITZ[2]
Howard University

FRED L. YAFFE
Eye Research Foundation, Bethesda

Adaptation to prismatic displacement was conditioned to the wearing of a pair of goggles by employing Taylor's alternation technique. Each alternation consisted of 2 3-min. training conditions. In one condition, *S* was exposed to the goggles and the prism; in the other, *S* was exposed to neither. Three groups of 13 *S*s were trained. They received either 1, 3, or 5 alternations. Pointing test measures designed to measure aftereffects and conditioned aftereffects were performed by each *S* at 0, 5, 10, and 20 min. after training. Otherwise, *S* sat quietly with closed eyes after training. Training time and testing time both produced significant effects. Aftereffects of adaptation exhibited a reminiscence effect and then decay, whereas the conditioned aftereffects exhibited neither.

When a prism displaces the viewer's visual field it initially causes errors in localization responses (effect). These errors decrease in magnitude (adaptation effect) after some appropriate practice by *S*. The adaptation effect measures are in turn taken to reflect an underlying psychological compensation (adaptation) to the optical disarrangement. Responses then made with the removal of the device exhibit an error in the direction opposite to the effect (aftereffect). For some time, aftereffects were assumed to be conservative estimates of adaptation effects and as an equally valid indicator of adaptation because, in the early studies which measured both, the magnitude of the former so nearly agreed with the magnitude of the latter (Rock, 1966). Conditioned adaptation studies, however, have indicated that this equality need not always hold (Kohler, 1964).

Conditioned adaptation studies usually have 2 major parts: a training period and testing periods. The training period is designed to produce an association between the adaptation and a previously neutral stimulus. This is achieved (*a*) by employing 2 alternating training conditions, one with normal vision and the other with vision modified by the optical device, and (*b*) by the systematic covariation with the training exposure conditions of other different processes, specifically the absence and presence of the neutral stimulus.

To date, 2 techniques have been developed to produce this alternation. In one (Kohler, 1964), *S* is exposed to a split visual field by having an optical device, a prism, in the upper half of the field and unobstructed normal viewing in the lower. Here the alternation produced is solely dependent upon a behavior of *S*, namely *S*'s changing the direction of his gaze. In the other technique (Taylor, 1962), the alternation of the training conditions depends upon the intervention of *E*, who simultaneously exposes *S* to the optical device and the neutral stimulus and later removes them. Conditioned adaptation effects are taken to be present when in the testing period the adaptation effects or aftereffects obtained with the neutral stimulus present are greater than those obtained with it absent.

Taylor (1962) produced differential conditioned adaptations by systematically covarying the training exposure conditions with the sensations produced by wearing spectacles that housed the optical device. With this procedure he conditioned the adaptation effect to right–left reversal and to the prismatically produced slant of horizontal surfaces. During testing he found that the adaptation effects obtained while wearing the spectacles were much larger than the aftereffects obtained with the spectacles absent.

Recently Kravitz (1972) refined the Taylor (1962) alternation training technique and associated the adaptation to prismatic displacement to the wearing of goggles in 240 min. of training. This study replicated Taylor's findings, namely, that there were larger adaptation effects with the goggles in place than aftereffects with them removed. It also demonstrated that aftereffects obtained while wearing the goggles without a prism were larger than those obtained without goggles. The magnitudes of these differences were taken as a measure of the conditioned adaptation to the goggles. Aftereffects obtained in the absence of the goggles are accordingly viewed as measuring a component of the total adaptation not under the control of the goggles as a conditional stimulus (CS). One current theoretical issue regards how adaptation in general and this component in particular should be viewed. However, for reference purposes we propose to provisionally label this component as "generalized aftereffect." One position holds that adaptation does not depend upon or necessarily result in learning (Mikaelian, 1963). The other holds that adaptation not only depends upon past experience (Held, 1961) but is due to learning (conditioning) processes (Taub, 1968). If the generalized aftereffect is a form of learning, then it could be expected to "decay" (Ebenholtz, 1969; Hamilton & Bossom, 1964) in a manner similar to that of conditioned adaptations. The present study tests this hypothesis.

Method

Apparatus. The displacement of the visual field was produced by a 20-diopter wedge prism mounted, base left, in the right frame of a pair of welder's goggles. The left eye of *S* was occluded at all times by an eye patch. A second pair of welder's goggles had an optically plain piece of glass in its right frame.

The testing apparatus was a vertically adjustable, horizontal platform, 152 cm. long and 66 cm. deep, which when raised to shoulder level allowed *S* to extend his arm easily underneath it. On the platform's near edge a biteboard apparatus was fixed. On the far side of the platform was a panel (102 cm. wide by 76 cm. high) perpendicular to *S*'s line of regard. The pointing test target was a vertically oriented black bar (6 × .6 cm.). It was presented in 2 positions: 6° to the right of *S*'s midline and 6° to the left, through a 76-cm.-long, horizontal, eye-level slit in the rear panel. The rear panel and the remainder of the apparatus were painted flat white. The *E* used a meter stick to determine *S*'s pointing responses.

Responses. A manual localization test was employed to measure the effects of training. It involved having *S* stand biting the biteboard, extending his right arm under the platform, and pointing with his right index finger. At the testing apparatus, *S* had his eyes closed at all times, except when making a pointing response. The pointing test measure was the mean of 4 pointing responses: 2 responses to each of 2 target positions. Each response required *S* to open his eyes and point at the apparent location of the target. The order of target position presentation was counterbalanced.

Test conditions. The pointing test was performed in 2 testing situations: In the first $(G/\bar{P})$, *S* wore the goggles (G) with plain glass $(\bar{P})$; in the second $(\bar{G}/\bar{P})$, *S* did not wear the goggles $(\bar{G})$ or the prism $(\bar{P})$.

Experimental design. Thirty-nine undergraduates drawn from Howard University introductory psychology courses served as paid voluntary *Ss*. They were assigned to 3 equal groups.

Each group was administered the same 6 main segments of the experiment, which were in order of occurrence: pretesting, training, and 4 posttest segments (A, B, C, and D). Figure 1 depicts the manner in which the 2 types of test situations were distributed among the first 3 segments of the experiment. The subscripted numbers affixed to each test condition indicate its order of occurrence. Each *S* went through the following sequence. First was the pretesting, which involved 2 test conditions: $(\bar{G}/\bar{P})_1$ and $(G/\bar{P})_2$. The *S* then received alternation training followed by Posttesting A. All the posttest segments had the same test condition sequence. The Posttest A sequence had 3 test conditions: $(\bar{G}/\bar{P})_3$, $(G/\bar{P})_4$, and $(\bar{G}/\bar{P})_5$. Posttest B immediately followed Posttest A. After Posttest B there was a 5-min. rest period followed by Posttest C. Posttest C was followed by a 10-min. rest period and then Posttest D. Thus, Posttests A, B, C, and D occurred 0, 5, 10, and 20 min. after the completion of training. During each rest period *S* sat quietly with eyes closed.

The effects of training and/or decay were determined by obtaining the difference between the pre- and posttesting measures of a given type of test condition.

Since all testing was under $\bar{P}$ (no prism) conditions, these differences (represented in Figure 1 by solid lines connecting the pretest conditions to the Posttest A conditions) resulted in aftereffect measures represented in Figure 1 by the circled d symbol appended to each solid line.

Thus, we obtained from each posttest segment 3 pointing test measures of aftereffects of adaptation. It was expected that the G aftereffects would be greater than the $\bar{G}$ aftereffects to the extent that the adaptation had become conditionally associated to the wearing of the goggles. The difference between these effects (indicated in Figure 1 as the

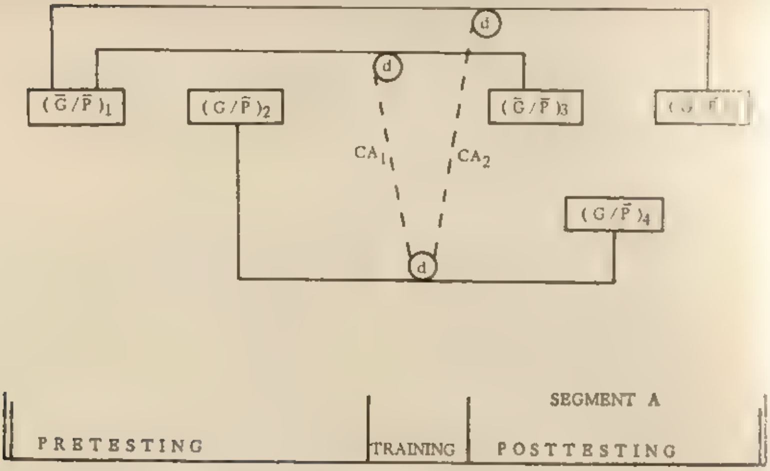

FIGURE 1. The pretest, training, and posttest (Segment A) sequence. (The solid lines represent differences between pre- and posttest conditions that result in the measurement of aftereffects [circled d] of adaptation. Dashed lines connecting circled d symbols represent differences between G [goggles present] and Ḡ [goggles absent] effects and result in the measurement of conditioned adaptation effects [CA_1, CA_2].)

dashed lines labeled CA_1 and CA_2 connecting the circled d symbols, Posttest A) are considered measures of conditioned adaptation (CA). The mean of these 2 measures (CA_e) constitutes a single estimate of the conditioned effects measured in the testing segment. The same calculations apply to all of the testing segments.

Training procedure. Each group (E_1, E_3, and E_5) was given alternation training designed to produce differential conditioned adaptation to the wearing of goggles. Group E_1 received 1 alternation; E_3, 3; and E_5, 5. The total training times of E_1, E_3, and E_5 were 6, 18, and 30 min., respectively. Each alternation consisted of 2 3-min. training exposures: In G/P, *S* wore the goggles (G) and was exposed to prismatically altered viewing (P); in Ḡ/P̄ the goggles were absent (Ḡ) and the viewing was normal and unaltered (P̄). The alternation was accomplished by having *S* sit with his eyes closed while *E* placed or removed the goggles. During each training exposure, whether G/P or Ḡ/P̄, *S* performed the same training task. The task consisted of viewing his right arm resting upon a vibrating armrest. Twice during each 3-min. segment, *S* was instructed to move his arm and hand to the left, center, right, and center of the arm rest. Otherwise, the arm rested passively (Kravitz & Wallach, 1966). Each alternation began with a G/P exposure and ended with a Ḡ/P̄ exposure.

RESULTS

The principal inquiries of this study were: (*a*) Will conditioned adaptation effects be produced by short forms of training; and (b) what is the relationship between the decay of generalized aftereffects and the decay of conditioned adaptation effects? Therefore, only Ḡ aftereffects and CA_e effects are presented in Table 1. Each Ḡ figure is the mean difference in degrees between the mean of the 2 Ḡ/P̄ posttest conditions of a segment and the corresponding pretest condition. The CA_e effects are a derived measure. They are the mean differences between the Ḡ and the G aftereffect measures. Each G measure (not presented in the table) is the mean difference between the pre- and posttraining measurements of the G/P̄ test conditions.

Individual *t* tests were performed on each of these mean effects to determine whether they were significantly different from zero. Inspection of Table 1 indicates that even with the short training times employed, significant conditioned adaptation effects were obtained. The grand mean CA_e effect, 1.5°, was significant, $t(38) = 4.43$, $p < .01$.

A 3-way (3 × 4 × 2) analysis of variance with 2 repeated factors was performed and is presented in Table 2 (Winer, 1962). The first factor was training groups (6, 18, and 30 min.); the second factor was testing time (0, 5, 10, and 20 min.); and the third

Note. Each $\bar{G}$ is the mean difference between the mean of the 2 $\bar{G}$ $\bar{P}$ (goggles and prism absent) posttest conditions of a segment and the corresponding pretest conditions. A minus signifies a $\bar{G}$ posttest deviation in the nonadaptive direction.) Each CA_c is the mean difference between the $\bar{G}$ and the G aftereffect measures. (The G measure is the mean difference between the pre- and posttraining measures of the $\bar{G}/P$ test conditions.)
* $p < .05$; deviations significantly different from 0; 2-tailed test.
** $p < .01$; deviations significantly different from 0; 2-tailed test.

factor was the comparison of aftereffects and conditioned aftereffects ($CA/\bar{G}$). The group effect was significant, F (2, 36) = 8.05, $p < .01$. A Newman-Keuls comparison of the group ordered means revealed that the 30-min. group produced significantly larger effects than both the 18- and 6-min. groups ($p < .05$), and that the 18-min. group was correspondingly larger than the 6-min. group ($p < .05$).

The time effect was also significant, F (3, 108) = 11.51, $p < .01$. A Newman-Keuls comparison of the time effects revealed that the immediate test was not significantly different than the 5-min. test. All other comparisons revealed significant decrements in effects with time ($p < .01$). However, these decrements are accounted for by the Time × $CA/\bar{G}$ interaction, which was the only other significant effect of the analysis, F (3, 108) = 4.02, $p < .01$. Although the CA_c trend is decreasing, a Newman-Keuls comparison of this component of the interaction revealed that these effects did not significantly change with time. The same comparison of the $\bar{G}$ effects (generalized aftereffects obtained with the CS absent) revealed significant changes as a function of time. Apparently the CA_c decay rate is slower than that of generalized aftereffects. The comparison of the immediate $\bar{G}$ effect to the 5-min. effect revealed a "reminiscence effect": The 5-min. effect was significantly larger (.7°) than the immediate effect ($p < .05$). The $\bar{G}$ effects then progressively decreased in magnitude with time. The 10- and 20-min. effects were both significantly smaller (1.0° and 1.7°, respectively) than the 5-min. effect ($p < .05$). The 20-min. effect was also smaller (1.0°) than the immediate effect ($p < .05$).

* $p < .01$.

Thus, an increase in the number of trials and training time does affect the magnitude of the conditioned adaptation effects and aftereffects obtained. Conditioned adaptation effects do not decrease in magnitude due to passive forgetting; generalized aftereffects obtained in the absence of the CS reveal at first an increment and then a progressive decrement with time.

Discussion

The CA_c effects of the present study indicate that relatively short periods of training can produce conditioned adaptation effects. An argument against this conclusion might be that these effects are due to some form of conscious correction by *S*. Such a correction would involve implicit verbal self-instruction regarding the effects of the prism, its contingencies, and a mode of corrective compensatory responding.

Evidence, however, does not support this contention. First, in postexperimental interviews most *S*s were unable to verbalize either what happened in the experiment or the displacement effects of the prism. All denied deliberate compensation during testing.

Second, the magnitude of the overall CA_c effects (1.5°) is so small relative to the prismatic displacement (11.6°) that an explanation of these effects in terms of conscious correction would constitute a gross extension of the meaning of that construct. We therefore conclude that the CA_c effects are not due to conscious correction and that they indicate that conditioning has been produced.

Aftereffects typically increase in magnitude with increasing training time (Hamilton, 1964). The results of the present study indicate that this relationship holds even under conditions of alternation training. In addition, we find that conditioned adaptation effects and generalized aftereffects both increase with increasing amounts of training and in this regard function similarly. Ebenholtz (1969) found that tilt aftereffects decay with time and that the rate of decrease was independent of initial magnitudes of effects. The lack of a Groups × Time interaction in the present study extends his finding to aftereffects obtained under alternation training. Ebenholtz also developed the comparator model of adaptation (Held, 1961) so as to account for the obtained decay of tilt aftereffects. However, that model, as presently formulated, cannot account for the reminiscence effect obtained with the $\bar{G}$ aftereffects in th[illegible] study. Moreover, the present effect repli[illegible] both in terms of time and direction that o[illegible] with monkeys (Taub, 1968). This [illegible] suggests that generalized aftereffects and [illegible] ad- aptation effects may be affected [illegible] more or less transient inhibitory proce[illegible] Other- wise, the decay of $\bar{G}$ aftereffects w[illegible] as expected. The adaptation as a form of learning hypothesis would lead to the deduction that generalized aftereffects and co[illegible] after- effects would decay similarly. Ou[illegible] lts do not confirm this deduction. Ra[illegible] they imply that the hypothesis must [illegible] dified if it is to remain viable. The n[illegible] ation would be such as to take into accou[illegible] fact that adaptation as a form of lea[illegible] and conditioned adaptation as a form o[illegible] rning function dissimilarly in some repects.

PERCEPTUAL UNITS IN SPEECH RECOGNITION [1]

DOMINIC W. MASSARO [2]

University of Wisconsin—Madison

The size of the sound stimulus employed in the first stage of speech processing was investigated in an attempt to determine the perceptual unit of analysis in speech recognition. It is assumed that the perceptual unit is held in a preperceptual auditory image until its sound pattern is complete and recognition has occurred. Vowels and consonant–vowel syllables were employed as test items in a recognition-masking task. The results show that recognition performance improved up to 200–250 msec. after presentation of the speech sound. The results were interpreted as evidence that the preperceptual auditory storage and perceptual processing of a speech sound does not exceed 250 msec., implying that some transformation of the speech signal must occur about every ¼ sec. Since the stimulus within this time period must function as a perceptual unit, perceptual units appear to be of roughly syllabic length.

The primary purpose of this study was to determine the size of the sound stimulus employed in the first stage of speech recognition. A listener has recognized (identified) a stimulus when he has determined that one of a possible set of alternatives was presented. Recognition of a stimulus is possible only if the information in the stimulus is sufficient to distinguish that stimulus from other possible stimulus alternatives. Recognizing speech continuously implies that each small portion of the sound-wave pattern uniquely determines a stimulus alternative. However, small portions of the acoustic input are not unique; there is no one-to-one mapping of stimulus to percept. Since the sound pattern must contain enough information for a consistent stimulus–percept mapping, larger chunks of the acoustic input are necessary for recognition.

Since the sound stimulus for speech recognition extends over time, the first part of the pattern must be held in some preperceptual form until the pattern is complete and recognition has occurred. Accordingly, it is assumed that the information in the sound pattern is held in a preperceptual auditory image and that the recognition process involves a readout of the information in that image. The duration of the preperceptual auditory image places an upper limit on the sound patterns that can be employed in the recognition process. Accordingly, to understand speech recognition, it is necessary to determine the maximum duration that information can be held in a preperceptual auditory image.

The minimal sound patterns that are usually recognized in continuous speech are referred to as perceptual units. In terms of the present analysis, the perceptual unit cannot exceed the duration of the image and must uniquely determine the appropriate perceptual response. The perceptual unit of analysis gives the perceptual system acoustic information that can be reliably correlated with information in long-term memory. The information in the unit is defined by a set of features that correspond to a list of features in long-term memory. The features made available by the stimulus are acoustic, whereas the list of features in memory is abstract. The recognition process must find a match between the acoustic features in the stimulus and a list of features in memory. The nature of perceptual units also provides information about the structure of long-term memory. A set of features in the acoustic signal indicates that the signal can be identified and can therefore be used to

integrate with other units so that meaning can be derived from the message.

The following studies were carried out to determine the size of perceptual units employed in speech perception. It is necessary, therefore, to determine the temporal course of processing speech stimuli and to estimate the effective duration of the preperceptual image. Vowels and consonant–vowel syllables were employed as test items in an auditory recognition masking task (Massaro, 1970b). In this task, a test stimulus is presented, followed by a masking stimulus that occurs after a variable silent interstimulus interval. In a typical experiment, the test signals are short tones differing in pitch, and the listener's task is to identify the higher tone as high and the lower tone as low. The masking tone is presented at another frequency and at the same loudness as the test tones. The results indicate that recognition performance improves with increases in the silent intertone interval, up to about 250 msec. (Massaro, 1970b, 1971, 1972c).

These results provide information about the preperceptual auditory image of the test tone and the vulnerability of the auditory image to new inputs. Given that the test tone lasted only 20 msec., some preperceptual image must have remained for the perceptual processing necessary to improve recognition performance with increases in the silent intertone interval. This improvement in recognition also indicates that the masking tone terminated perceptual processing of the image. Since recognition performance leveled off at about 250 msec., the image effectively decayed within this period. Using this paradigm with speech stimuli should make it possible to determine the duration of preperceptual images and the processing time required for speech stimuli.

Experiment I

The first experiment demonstrates that the recognition of a short speech stimulus is not immediate, but rather requires time for perceptual processing. Perceptual processing refers to the analysis of physical features in the sensory input in order to recognize the stimulus. A measure of perceptual-processing time might be found in the durations of vowels in normal speech which are in the range of 150 [illegible] msec. (Fletcher, 1953; House, 1961; Peterson & Lehiste, 1960). Since the pattern of sound-pressure fluctuations in a steady-state vowel repeats at the speaker's fundamental frequency, the extended duration of the vowel might be necessary for processing the information available in the vowel presentation. Vowels presented for very short durations can be identified if followed by a silent retroactive interval (Gray, 1942; Suen & Beddoes, 1972). However, if processing is interfered with by following the short test-vowel presentation with another speech sound, the test vowel should not be identified. This result would provide evidence that the duration of the vowel in normal speech allows time for processing, since the extended duration of the vowel protects it from later speech until recognition has been completed.

The *S*s were required to recognize a test vowel. On each trial, 1 of 2 vowels could be presented with equal probability. A second vowel, referred to as the masking vowel, followed the test vowel after a variable silent intervowel interval. It was assumed that the perceptual processing necessary for recognition of the test vowel could take place during the test-vowel presentation and the silent interval afterwards, but *not* during the masking-vowel presentation.

Method

Subjects. Three young adults from the University of Wisconsin community were employed as *S*s.

Procedure. The vowels of a male speaker were first recorded at the same fundamental frequency and amplitude. A steady-state segment of each vowel was stored digitally by a computer-controlled analog-to-digital converter. During this experiment, the vowel segment was played back, using a digital-to-analog converter. In the recognition masking task, the vowels /i/ as in *heat* and /I/ as in *hit* were employed as test items. The duration of the test vowel was 20 msec. The silent intervowel interval lasted 0, 20, 40, 80, 160, 250, 350, or 500 msec. The masking stimulus was a 270-msec. nonsense vowel made up of 2 alternating vowel segments. These 2 segments were taken from the

vowels /a/ as in *hat* and /U/as in *put* and lasted 45 msec. each.

The *Ss* were tested simultaneously in a sound-insulated chamber. All experimental events were controlled by a PDP-8 computer. The vowels were presented binaurally over matched headphones (Grason-Stadler Model TDH-39) at a normal listening intensity (about 80-db. SPL). An *S* recorded his decision by pressing 1 of 2 push buttons, labeled i and I, respectively. Following the 2.5-sec. response period, feedback was given by illuminating a small light for 500 msec. above the correct response button. The intertrial interval was 2 sec.

On every trial, *S* heard a test vowel, followed in turn by a variable silent interval and the masking vowel. He identified the test vowel as i or I and was then informed of the correct answer for that trial. The *Ss* had 1 day of practice identifying the test vowels without a masking vowel and 2 days of practice with a masking vowel before the experiment itself, which consisted of 2 days of 3 sessions each. There were 400 trials/session, and *Ss* did not respond to the first 5 trials of each session. Since all experimental conditions were completely random, memory and decision factors were reasonably constant. The results, then, indicate the temporal course of the perceptual or identification process.

Results

The results of the experiment, presented in Figure 1, show that for each *S*, recognition improved from near chance to almost perfect performance with increases in the silent intervowel interval. The results indicate that an auditory image remained after the first vowel and was processed during the intervowel interval for recognition. The second vowel was effective in terminating the perceptual processing of the image. Figure 1 shows that the processing time necessary for asymptotic recognition differed for the 3 *Ss*. Two *Ss* (KB and MF) required about 180 msec. for optimal recognition. In contrast, the third *S* (DC) was able to identify the test vowel with only 80 msec. of additional processing time after its presentation.

These results do not necessarily estimate the duration of the preperceptual image or the perceptual processing time in typical vowel identification. Since performance reached asymptote at essentially perfect recognition, the recognition process could have been complete before the image decayed. To estimate the duration of the image, recognition accuracy must reach

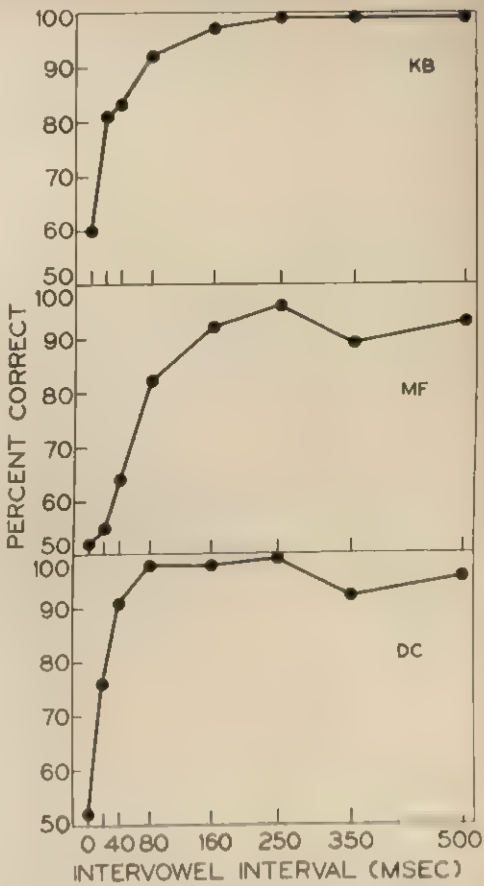

FIGURE 1. Percentage of correct test-vowel identifications for *Ss* KB, MF, and DC as a function of the duration of the silent intervowel interval: Experiment I.

asymptote below perfect performance. In the present study, the test vowel was 1 of only 2 possible vowels. With only 2 alternatives, *S* can probably make his decision very rapidly, since fewer acoustic features of the vowels need be processed for accurate recognition. With a larger number of alternatives, however, *S* would have to process more features before reaching a decision. Accordingly, increasing the number of alternatives in this task should increase the effective perceptual-processing time up to the duration of the auditory image. Accordingly, Experiment II was carried out with 4 test alternatives in the recognition masking task.

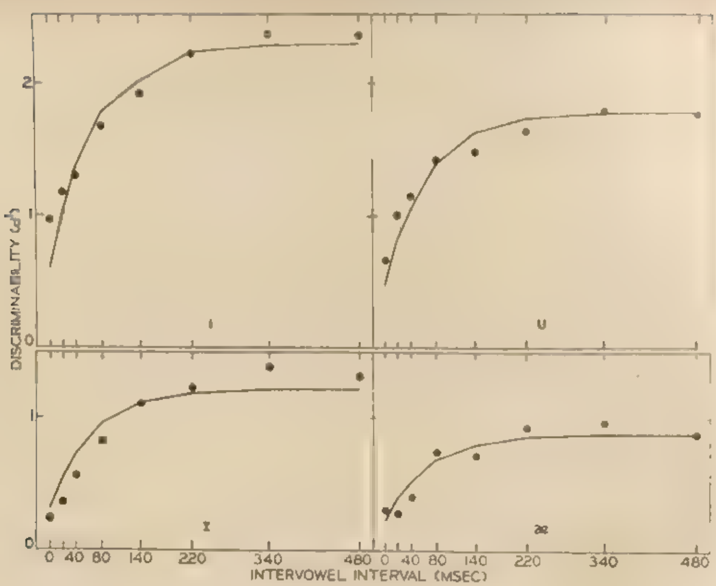

FIGURE 2. Discriminability values for the 4 test vowels as a function of the silent intervowel interval: Experiment II. (The lines are drawn through the predicted points given by Equation 1.)

EXPERIMENT II

Method

Subjects. Twelve University of Wisconsin undergraduates fulfilling a course requirement were tested for 5 days.

Procedure. In Experiment II, 4 vowels recorded by a female speaker were employed as test items. The fundamental frequency of the vowels was 192 Hz. The test alternatives were the vowels /i/ as in *heat*, /I/ as in *hit*, /a/ as in *hat*, and /U/ as in *put*. The duration of the test vowel was 20 msec. The silent intervowel interval lasted 0, 20, 40, 80, 140, 220, 340, or 480 msec. The masking stimulus was also chosen randomly from the 4 vowels, /i/, /I/, /a/, and /U/, and also lasted 20 msec.

Four *S*s were tested simultaneously in separate sound-attenuated rooms. All experimental events were controlled by a PDP-8L computer. The vowels were presented binaurally over matched headphones (Grason-Stadler TDH-49) at between 58- and 67-db. SPL. Each *S* recorded his decision by pressing 1 of 4 push buttons, labeled HEAT 1, HIT 2, HAT 3, and PUT 4, respectively. Following the 2.5-sec. response period, feedback was given by presenting the digits 1, 2, 3, or 4 on a visual display (IEE readout) for 500 msec. The intertrial interval was 2 sec. There were 2 300-trial sessions on each of 5 days. On the first day, *S* identified the test vowel without the masking vowel present. On Days 2, 3, 4, and 5 the experiment proper was carried out. Presentation of the 4 test alternatives, the 4 masking alternatives, and the 8 intervowel intervals was completely random, and each condition was programmed to occur equally often. Day 2 wa[illegible]ted as practice, so that the results are taken [illegible] the last 3 experimental days.

Results

The results were analyzed in terms of a signal detectability framework to provide a measure of vowel discriminability, d', which would be relatively independent of decision biases. It is possible to derive a measure of recognition performance for each of the 4 test vowels. The probability of identifying a vowel correctly is designated a hit, and responding with that vowel alternative to any other test alternative is designated a false alarm. For example, the probability of responding i given the test vowel /i/, $p(\mathrm{i}|\mathrm{i})$, would be a hit, whereas the probability of responding i given any other alternative, $p(\mathrm{i}|\bar{\mathrm{i}})$, would be a false alarm. The d' measure derived from these probabilities would be the index of discriminability for the vowel /i/. The d' values were obtained from the hit and false alarm rates (averaged across *S*s) in Elliot's (1964) tables.

Figure 2 presents the d' values for each test vowel as a function of the intervowel

interval. Identification of each vowel improved with increases in the silent interval between the test and masking vowels. These results can be used to estimate the duration of the preperceptual image and perceptual-processing time, since recognition reached asymptote below perfect performance. Since performance did not improve beyond an intervowel interval of 220 msec., the image could have decayed in this period. Figure 2 also shows that the test vowels were not recognized equally well, implying that the alternatives differed in discriminability. The rank ordering from least to most discriminable was /a/, /I/, /U/, and /i/.

The continuous lines in Figure 2 are drawn through the predicted points given by a perceptual-processing model (Massaro, 1970a), which assumes that readout of the information in the preperceptual image increases in a negatively accelerating manner with increases in processing time. More specifically, the perceptual strength of an item, as measured by its discriminability, d', follows an exponential growth function of time:

$$d' = \alpha(1 - e^{-\theta t}). \qquad [1]$$

The measure d' is the discriminability of the item after a presentation time of t sec. In the model, presentation time includes both the duration of the test item and the silent interval before the onset of the masking stimulus. Equation 1 indicates that the perception of a test item approaches an asymptote α at a rate of θ.

Each test vowel is assumed to function as a perceptual unit and therefore has a number of distinctive features that correspond to a feature list in long-term memory. The rate at which these features are processed is reflected in the value of θ. A vowel with a large number of distinctive features would be expected to have a large α value. A noisy or unclear vowel would have few distinctive features and a small α value. Thus, the α value can be thought of as an index of the number of discriminable features of a vowel.

According to the model, the overall differences found in identifying the test vowels should reflect differences in α, the measure of discriminability. However, θ, the rate of processing the information in the vowel, should be independent of α. In all cases, the number of features processed in any unit of time should be a constant proportion of the number of features that remain unprocessed. Equation 1 was applied to the observed results in Figure 2 by estimating a different parameter value of α for each test vowel and a single value of θ. As can be seen in Figure 2, the model describes the results fairly accurately. Thirty data points are predicted with only 5 parameter estimates. The parameter estimates of the α values for /i/, /I/, /a/, and /U/ were 2.29, 1.31, .88, and 1.77, respectively. The estimated value of θ was 15.17.

Table 1 presents the average recognition performance for the different test stimuli as a function of the masking vowel. As can be seen in the table, all masking vowels were equally effective in terminating perceptual processing of the test vowel. Of special interest is the finding that a vowel can mask itself. This means that *S* did not discriminate trials on which the test and mask were the same vowel. Since identification of the test vowel requires perceptual-processing time, it cannot be accurately compared to the masking vowel until it is recognized. The masking vowel overwrites the test vowel effectively, leaving very little information about the test-vowel presentation.

The results show that perception of a short vowel presentation improves with

TABLE 1

AVERAGE PERFORMANCE (MEASURED IN d' VALUES) FOR TEST VOWELS AS A FUNCTION OF MASKING VOWELS

Test stimulus	Masking stimulus			
	/i/	/I/	/a/	/U/
/i/	1.76	1.78	1.78	1.62
/I/	.78	.95	.96	.78
/a/	.56	.66	.23	.66
/U/	1.15	1.33	1.22	1.75
Average	1.06	1.18	1.05	1.20

increases in the silent interval after its presentation. This result provides evidence for the assumption that the duration of vowels in normal speech provides time for perceptual processing. However, increasing the duration of a vowel could also increase the amount of information in the vowel presentation. Increasing the duration of a vowel increases the information in the stimulus if one analyzes the frequency–amplitude spectrum of the steady-state vowel. With a short vowel stimulus, the distributions of energy around the respective formants are fairly large, and increasing the duration of the vowel would decrease the variance of the distributions. Accordingly, to measure the relative contribution of processing time and stimulus information in vowel perception, perception of a short vowel followed by a silent interval was compared to perception of that same vowel left on for the processing interval before presentation of the masking vowel.

Experiment III

Method

Subjects. Eight undergraduates fulfilling a course requirement at the University of Wisconsin served as *S*s for 5 days.

Procedure. The 4 test alternatives used in Experiment II were also employed in this study. The vowels were first modified digitally to give exactly the same steady-state loudness (65-db. SPL). Since the vowels had a fundamental frequency of 192 Hz., 5 fundamental segments gave a stimulus duration of 26 msec. In the continuous-processing conditions, vowels had to be presented at durations that exceeded our computer storage capacity. Accordingly, we stored 26 msec. of each vowel and repeated this segment until the desired duration was presented. The masking vowel was a 208-msec. continuous nonsense vowel made up of 2 repetitions of the 4 test vowels, /i/, /I/, /a/, and /U/, played for 26 msec. each.

On the first day of the experiment, *S*s listened to the test vowels played at durations of 208, 104, and 52 msec., respectively, in 3 successive 300-trial sessions. Feedback was given simultaneously with the test-vowel presentation. The experiment proper was carried out on the following 4 days. In the silent-processing condition, the test vowel was presented for 26 msec., followed in turn by a silent interval (0, 26, 52, 78, 130, 182, 260, or 390 msec.) and the masking vowel. In the continuous-processing condition, the test vowel was presented for 26, 52, 78, 104, 156, 208, 286, or 416 msec., followed immediately by the masking vowel. All experimental conditions (4 Test Vowels × 2 Processing Conditions × 8 Processing Intervals) were completely random in a given session and were programmed to occur equally often. Therefore, on every trial, *S* heard a test vowel of variable duration, followed in turn by a variable silent interval and a masking vowel. Following a 2-sec. response period, feedback was presented. The intertrial interval was 1 sec. All other procedural details were similar to Experiment II. Two 300-trial sessions were given, and the first 5 trials on each day were [illegible]d in the data analysis.

Results

The results shown in Figures 3, 4, 5, and 6 present discriminability values for each vowel as a function of processing time and the silent and continuous conditions. For every vowel, identification was better when the vowel was left on for the processing interval than when a 26-msec. vowel was followed by a silent-processing interval. More specifically, for all test vowels, performance reaches asymptote at a higher level of performance for the continuous- than for the silent-processing condition, suggesting that there was more stimulus information in the test vowel in the former than in the latter processing condition. Furthermore, the results also indicate that performance reaches asymptote at the same processing interval for the silent- and continuous-processing conditions. Accordingly, it appears that the rate of processing the information in the test vowel did not differ under the 2 processing conditions.

This interpretation of the results can be described in the framework of the perceptual-processing model. We first assume that a 52-msec. vowel produces more information than a 26-msec. vowel, but that the information in a vowel presentation does not increase with increases in duration beyond 52 msec. It follows that the continuous condition should only have one value of α at test vowel durations of 52 msec. or more. We assume that this α value is some constant K, times the α value for the corresponding 26-msec. vowel presentation. Accordingly, to obtain the theoretical predictions, it is necessary to estimate a different α for each of the 4 test vowels, the constant K, and a value

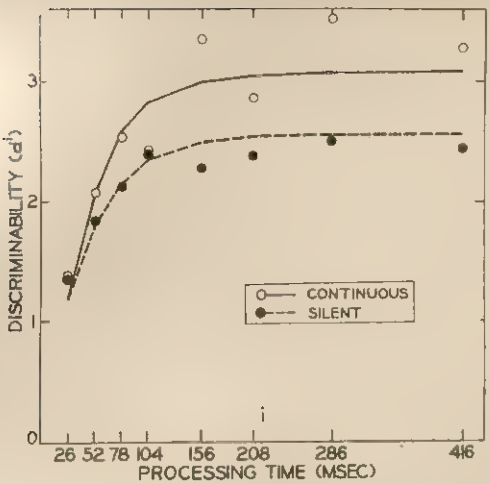

FIGURE 3. Discriminability values for the test vowel /i/ as a function of processing time during the continuous vowel presentation or the silent interval after a 26-msec. vowel presentation: Experiment III. (The lines are drawn through the predicted points given by Equation 1.)

for θ, the rate of perceptual processing, which should be constant under both the silent and continuous tone conditions.

The predicted curves are given by the continuous lines in Figures 3, 4, 5, and 6. The model does a reasonably good job of describing the data, considering the fact that 64 points are predicted by estimating only 6 parameters. The parameter values for α were 2.57, 1.41, 1.24, and 1.91 for the vowels /i/, /I/, /a/, and /U/, respectively. The estimated value for K was 1.20, and the value for θ was 23.77.

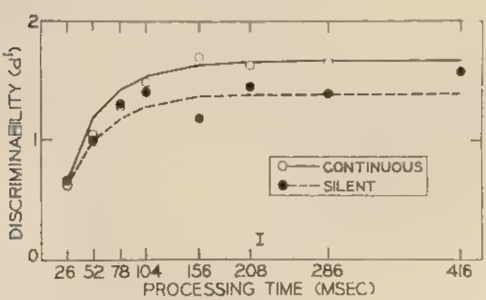

FIGURE 4. Discriminability values for the test vowel /I/ as a function of processing time during the continuous vowel presentation or the silent interval after a 26-msec. vowel presentation: Experiment III. (The lines are drawn through the predicted points given by Equation 1.)

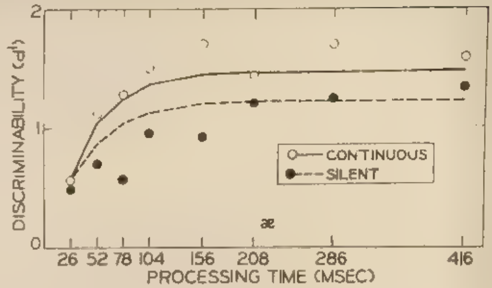

FIGURE 5. Discriminability values for the test vowel /a/ as a function of processing time during the continuous vowel presentation or the silent interval after a 26-msec. vowel presentation: Experiment III. (The lines are drawn through the predicted points given by Equation 1.)

In the silent-processing condition, recognition performance improved with increases in the silent interval, leveling off after roughly 200 msec. It might therefore be concluded that the preperceptual image of the test vowel decayed within this period. However, recognition performance reached asymptote at the same time in the continuous vowel condition. In this case, the image should not have decayed, since the test vowel was still being presented. It appears that recognition leveled off because S processed all the information available in the stimulus in the first 200 msec. In terms of the perceptual-processing model presented here, the rate of processing was

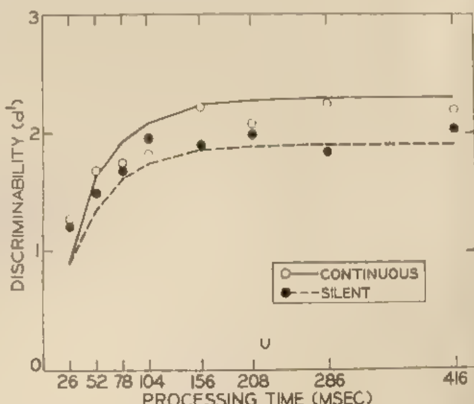

FIGURE 6. Discriminability values for the test vowel /U/ as a function of processing time during the continuous vowel presentation or the silent interval after a 26-msec. vowel presentation: Experiment III. (The lines are drawn through the predicted points given by Equation 1.)

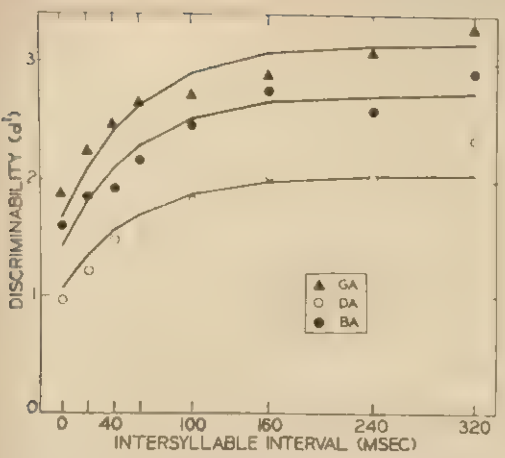

FIGURE 7. Discriminability values for the 3 test syllables as a function of the silent intersyllable interval: Experiment IV. (The lines are drawn through the predicted points given by Equation 1.)

large enough that performance reached asympote within 200 msec. It is possible that further increases in the number of test alternatives will differentially enhance performance in the continuous- relative to the silent-processing condition.

The results indicate that perceptual processing of a continuous vowel presentation continues for about 200 msec. This processing is terminated by a masking-vowel presentation. These results support the idea that the extended duration of the vowel in continuous speech allows time for perceptual processing, so that the vowel can be identified. The processing time during the steady-state vowels could also provide time for recognition of some consonants. The stop consonants are characterized by rapid transitions in the formants of the acoustic signal (Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967). The stop consonants /g/, /d/, and /b/ can be distinguished from each other by the second formant transition, which varies as a function of place of articulation (Delattre, Liberman, & Cooper, 1955). It has been argued that the stop consonant could not be recognized while it is presented, but would require some silent time or steady-state period for recognition to take place (Massaro, 1972b).

This analysis implies that the stop consonant–vowel (CV) transition would function as a perceptual unit in speech perception. If the vowel is integrated with the CV transition, the extended duration of the vowel in normal speech would provide time for perceptual processing. Accordingly, the first part of the CV pattern probably could be identified if it is presented alone and followed by a silent interval. However, if the short CV syllable were followed by a speech sound that could not be integrated with it, perception should be disrupted, and backward recognition masking should occur. To test this, we took the CV transitions of 3 stop CV syllables and used these as test items in our backward-masking experiment.

EXPERIMENT IV

Method

Subjects. Six University of Wisconsin undergraduates fulfilling a course requirement were tested for 5 days.

Procedure. Three CVs were employed as both test and masking stimuli. The CVs were BA, DA, and GA (A as in *box*). The 2 formant CVs were synthesized at Haskins Laboratory[3] and recorded digitally for playback during the experiment. Enough of the CV syllable was presented for it to sound speechlike. Each CV syllable was of 42-msec. duration (30 msec. of transition plus 12 msec. of steady-state vowel) and was presented at 76-db. SPL. On each trial, 1 of the 3 CV syllables was presented, followed in turn by a variable interval and 1 of the 3 syllables. The silent intersyllable interval lasted 0, 20, 40, 60, 100, 160, 240, or 320 msec. Each *S* recorded his decision by pressing 1 of 3 push buttons labeled GA 1, DA 2, and BA 3, respectively. Following the 1.5-sec. response interval, feedback was provided by visually presenting the digits 1, 2, or 3 for 500 msec. The intertrial interval was 1.5 sec. Presentation of the 3 test alternatives, 3 masking alternatives, and 8 intersyllable intervals was completely random. The alternative GA could occur 2 out of 8 times and BA and DA each occurred 3 out of 8 times. All other procedural details were the same as in Experiment II.

On the first day, *Ss* identified the test syllable without the masking syllable present for 300 trials. The masking stimulus was presented in the second session. On Days 2, 3, 4, and 5, the experiment proper was carried out. There were 2 300-trial sessions per day. Only the results of Days 3, 4, and 5 were included in the data analysis.

[3] David B. Pisoni kindly provided a recording of the original unshortened syllables.

Results

The results, presented as in Figure 7, show that identification performance improved with increases in the silent intersyllable interval for all 3 CVs. The continuous lines are drawn through the predicted points given by Equation 1. Four parameter values were estimated: an α value for each CV test alternative, and a value of θ. The parameter estimates were 3.18, 2.06, and 2.75 for the values for GA, DA, and BA, respectively. The parameter estimate for the rate of perceptual processing, θ, was 17.28. Table 2 shows that the similarity between the test and masking stimuli did not systematically affect identification performance. However, BA produced less overall interference than GA or DA as a masking stimulus. This result might reflect the fact that the low frequencies of the syllable BA are less effective in terminating perceptual processing of an earlier CV presentation.

TABLE 2

AVERAGE RECOGNITION PERFORMANCE (MEASURED IN d' VALUES) FOR TEST SYLLABLES AS A FUNCTION OF MASKING SYLLABLES

Test syllable	Masking syllable		
	GA	DA	BA
GA	3.13	2.48	2.32
DA	1.40	1.58	1.94
BA	1.66	2.38	3.18
Average	2.10	2.22	2.72

DISCUSSION

These studies were carried out to determine the size of perceptual units employed in speech perception. It was argued that the perceptual unit could not be larger than the temporal life of a preperceptual image of the speech stimulus. If the information in the image decays before it is synthesized, recognition would not be possible. The results indicate that processing the speech stimuli employed here occurs within 200–250 msec. after the stimulus presentation. Accordingly, some transformation of the speech signal must occur about every ¼ sec. The stimulus within this time period must function as a perceptual unit. There must be sufficient information in this signal (and in the context in normal speech) for contact with information in long-term memory. To the extent the present studies simulate the processing of real speech, it might be concluded that the first stage of speech recognition must operate on acoustic segments that are of less than 250-msec. duration. If this is the case, perceptual units appear to be of roughly syllabic length, as suggested by Huggins (1964) and Massaro (1972b).

There are at least 2 apparent difficulties with assuming that the first stage of recognition involves a transformation or synthesis within 250 msec. after a sound pattern is presented. The first is that the utilization of auditory information occurs across much longer temporal periods. The memory for the quality of a speaker's voice requires an auditory memory that can last indefinitely. The interpretation of prosodic information such as stress requires an auditory memory that lasts for the length of a phrase or sentence. Most importantly, the recognition of sound patterns depends on an auditory memory for those sound patterns or even other sound patterns by the same speaker. For example, Ladefoged and Broadbent (1957) showed that the acoustic characteristics of some vowels of a speaker influenced the recognition of other vowels by the same speaker. Accordingly, the listener must have remembered some of the auditory characteristics of the vowels for longer than 250 msec. The auditory memory illustrated by these examples, however, is not preperceptual, but is auditory information that has been actively synthesized.

Massaro (1972a, 1972b) has distinguished between two stages of auditory information processing which involve preperceptual and synthesized auditory storage, respectively. The first stage involves recognition of a sound pattern held in a preperceptual auditory image. The recognition of the sound pattern produces a synthesized auditory percept in synthesized auditory storage. Synthesized auditory storage has a much longer life span than preperceptual images and could be responsible for auditory memory effects that operate over longer time periods than are given by preperceptual auditory storage. Accordingly, the auditory storage responsible for memory for voice quality, the Ladefoged and Broadbent (1957) effect, and for interpreting prosodic features of a sentence, is not preperceptual, but is at the level of synthesized auditory storage. (For a more complete discussion of the differences in pre-

perceptual and synthesized auditory storage, see Massaro, 1972a, 1972b.)

The second problem is that it is well known that the acoustic sound pattern corresponding to a syllable changes with changes in the speaker, the rate of speaking, the stress patterns, and (most importantly) the influence of neighboring syllables (Fant, 1962; Ohman, 1966). However, this problem is not unique to speech recognition, but is also the major deterrent to the development of a recognition device for handwritten text. This observation tells us that the representation of a perceptual unit in long-term memory must be a highly flexible one, with a number of normalization algorithms that operate on the sound-pattern input. Luckily, in normal speech, context or redundancy significantly reduces the number of valid alternatives for each sound pattern. The sound pattern can, therefore, be noisy, since redundancy reduces the number of acoustic features that are necessary to recognize the pattern correctly.

EFFECTS OF SAME–DIFFERENT PATTERNS ON TACHISTOSCOPIC RECOGNITION OF LETTERS[1]

ROBERT P. INGALLS[2]

California State University, Chico

Two experiments investigated whether *S*s recognize that letters are physically identical prior to naming them, or whether the processes of naming and physical matching occur in parallel. Stimuli consisting of 3 letters were presented tachistoscopically at a duration such that *S*s could identify all 3 letters about half the time. The *S*'s task was to name the letters. Some stimuli had all 3 letters the same, some had all 3 letters different, and some had 2 the same and 1 different. There was no difference in recognition performance between the condition with all 3 letters the same and the condition with all 3 letters different, suggesting that the physical matching process and the naming process are not sequential. However, recognition of letter patterns with the first 2 letters the same and the last letter different was much lower. The results were replicated with number stimuli.

A given pattern can be categorized in numerous different ways. For example, the pattern A can be processed as a letter with a certain sound, as a vowel, as a part of a word, or simply as a physical pattern consisting of 2 oblique lines with a horizontal line connecting them. A series of experiments by Posner and Mitchell (1967) showed that it takes longer to perform some categorizations than it does to perform others. Posner and Mitchell asked *S*s to decide whether 2 letters were the same or different, with the dependent variable being reaction time, and they found that physical matches took less time than did name matches, and name matches took less time than did matches based on the consonant–vowel distinction. A question which immediately comes to mind is how the various levels of categorization are related. There are 2 basic possibilities: they can be connected serially (sequentially), that is, physical processing is done first, and the information from physical processing is used to perform higher level categorizations such as naming; or they can be connected in parallel, essentially independently of one another.

The position that the 2 levels are sequential was taken in a study by Beller (1970), who based his thinking on Neisser's (1967) theory. Beller equates Posner and Mitchell's (1967) Level 1 processing to Neisser's concept of preattentive mechanisms, while Level 2 corresponds to figural synthesis and pattern recognition. To verify his approach, Beller used the assumption that preattentive processes are carried out in parallel. If Level 1 (physical match) is done in parallel, then it should not matter how many items were presented; the time needed to classify them all as same or different based on a physical match would be the same. His stimuli consisted of 2, 4, or 8 letters which *S* had to classify as same or different according to their name, as in Posner and Mitchell's Level 2 instructions. There were 2 interesting conclusions to his study. The first was that the times required to make physical matches were the same regardless of the number of letters in the stimulus; i.e., it took no longer to classify 8 letters as physically identical than it did to classify 2. These data provide strong support for the assumption of spatiotemporal parallelism in Node 1 processing. The second conclusion was that when all the stimuli were physically identical, *same* response times were faster than

[1] This research is based on a doctoral dissertation submitted to the University of Connecticut. The author is indebted to his committee, Michael Turvey, David Zeaman, and Donald Dickerson, for their invaluable advice and assistance throughout. The equipment was purchased through University of Connecticut Research Foundation Grant 102.

same response times when the stimuli differed physically but had a common name, even though the instructions in all cases were to judge on the basis of name similarity rather than physical similarity. This observation supports Beller's contention that the 2 levels are operationally serial because, apparently, once *S* recognizes that the letters are physically identical, he does not have to name each one even though his instructional set is to do so.

The purpose of the present experiments is to investigate the question of whether the physical match subsystem necessarily precedes the naming process. The general procedure was to present tachistoscopically a series of stimuli, each consisting of a 3-letter (or 3-number) array, followed by a masking stimulus. The time between the onset of the stimulus pattern and the onset of the mask was manipulated so that each *S* was able to report the 3 letters correctly about half the time. Previous research indicates that the amount of time that *S* has available to read out information from the stimulus is determined by the interval between the onset of the stimulus and the onset of the mask (see Kahneman, 1968, for a general review). Of course, this does not mean that no processing occurs after the mask comes on but rather that raw stimulus information is no longer available. Some of the stimuli had all 3 items the same, others had all 3 items different, and others had 2 the same and 1 different. The dependent variable was the percentage of letters correctly identified in each condition. If physical matching is an integral part of the preattentive processes as suggested by Beller (1970) and Neisser (1967), performance in the condition with all 3 letters the same should be better than performance in the case with all 3 letters different, with the other conditions in between these 2, because the preattentive mechanism would first detect the physical similarity of the 3 letters. This information would facilitate recognition because *S* would only have to identify any 1 of the 3 letters in order to get all 3 correct. If, however, the physical matching level and the naming process operate in parallel, then there should be no difference between the various conditions.

Experiment I

Method

Design. The *S*'s task was to identify [illegible] series of stimuli, each consisting of 3 letters, pre[illegible]ted on a Gerbrands 3-channel tachistoscope. Th[illegible] were 5 conditions in the experiment. In [illegible]ndition (AAA) all 3 letters were the same [illegible] econd condition (AAB) the first 2 letter[illegible] same and the last letter was different. I[illegible]d condition (BAA) the last 2 letters were [illegible] with the first letter different. In the fou[illegible]dition (ABA) the first and third letters were [illegible]e and the middle letter was different. In the [illegible]dition (ABC) all 3 letters were different. Ea[illegible]eived all stimuli in all conditions. The depend[illegible]riable was the proportion of letters correctly [illegible]ned in each of the 5 conditions.

Subjects. The *S*s were 15 undergrad[illegible]t the University of Connecticut who participated in the experiment for approximately ½ hr. each for course credit.

Apparatus and procedure. The apparatus was a Gerbrands T-3B-1 3-channel tachistoscope. Each trial was initiated by *S* pressing the start button. Immediately, the first field came on for 500 msec.; it consisted of 2 horizontal lines centered in the display, which indicated where the letters were going to be. The luminance was .1 ftL. as measured by a Spectra brightness spot meter. The second field came on immediately at the offset of the first and contained the letters to be identified. The duration for the second field varied between *S*s and [illegible] determined in the pretraining as the duration at which *S* was making 50% correct responses. The mean display time for the second field was 68 msec. with a standard deviation of 13.6. The third field was a mask made up of a series of interlocking circles and was in the same location as the letters. It came on immediately at the offset of the second field and stayed on for 50 msec. The luminances of the second and third fields were identical at 1.5 ftL.

Stimuli. The stimuli consisted of 50 4 × 6 in. cards, each of which contained 3 capital letters produced by Letraset 48 pt. Futura Medium. Only 10 of the 26 letters were used, C, D, H, L, M, N, P, R, S, and T. In the apparatus, each letter filled approximately 46′ of visual angle, and a display of 3 letters had a visual angle of approximately 2°51′. Each letter was used equally often in each condition to the extent that this was possible. There were 10 stimuli in Condition AAA, 5 in Condition AAB, 5 in Condition BAA, 10 in Condition ABA, and 20 in Condition ABC. The stimuli were divided randomly into blocks of 5 each, each block containing 1 of each condition to the extent that this was possible. The 10 blocks were then ordered randomly and each *S* was begun on a different block. In addition each *S* was given pretraining on stimuli identical to those used in the experiment, with the same proportion of each condition as in the actual experiment; i.e., 40% of the pretraining stimuli were of the ABC type, 20% were AAA pattern, 10% were BAA, etc.

[illegible]he purpose of the pretraining was to stabilize the [illegible]ance and to determine for each S that dura[illegible] which his performance was 50%. The num[illegible] of pretraining trials needed for this varied, with [illegible]an of 48.9 pretraining trials per S (SD = 12.4). [illegible] S said his response aloud immediately at the [illegible] each trial. The Ss were required to guess if [illegible] were not sure of the answer, and they had been [illegible]old before the experiment which 10 letters were to be used. If S's response was wrong, he was told what the correct letters had been. The purpose of this feedback was to acquaint him with the possible combinations of letters and the approximate proportions of each. It had been determined in pilot work that Ss tended to guess 3 different letters each time without this feedback, and so it was necessary to indicate that some stimuli might have all 3 letters the same and that others might have 2 the same.

Results

Figure 1 shows the mean percentage correct for each condition and position of the letter (first, second, or last). Averaging across positions, although performance in the AAA condition was slightly better than performance in the ABC condition as predicted by the Beller (1970) – Neisser (1967) model, this difference was negligible. The only stimulus condition which appeared to differ widely from the others was the AAB condition, in which performance was inferior. An analysis of variance indicated that both main effects of position and condition and the interaction between them were significant: for condition, F (4, 196) = 12.41, $p < .001$, for position, F (2, 196) = 51.46, $p < .001$, and for the interaction, F (8, 196) = 2.93, $p < .01$.

A Tukey test was done to determine which conditions differed significantly from each other. The only finding here was that the AAB condition differed reliably from the other 4 conditions at the .01 level. The difference between the AAA and ABC conditions did not even approach significance. Another Tukey test on paired comparisons between positions averaged across condition indicated that performance in the first position differed from performance in the other 2 at the .01 level, while the difference between Position 2 and Position 3 approached significance at the .05 level. The significant interaction appears to be due primarily to the fact that the condition effect (performance in the AAB condition being inferior to performance in the other conditions) was found only in the last 2 positions.

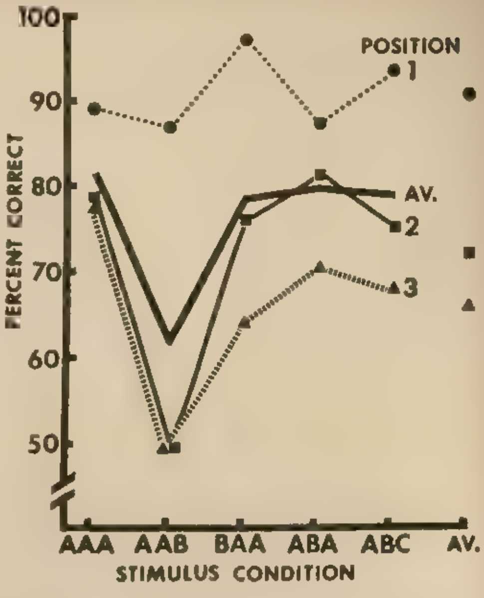

Figure 1. Percentage of letters correctly identified for each condition and position, Experiment I. (The A–B combinations represent the 5 same–different patterns. Av. = average.)

An analysis of the kinds of errors that were made was done to see if it would provide further clues regarding the mental processes involved in this task. The results are shown in Table 1. If the Beller (1970) model is taken literally, Ss should be able to detect the same–different pattern of the stimulus (i.e., all letters the same; first 2 letters same, last different; or whatever) before identifying the actual letters. Thus, there should be many cases where the response had the correct same–different pattern but missed one or more of the letters. The error analysis indicated that this was not the case. Many errors involved Ss getting all the letters correct but in the wrong order (17% in the ABC condition, 7% in the ABA condition, 20% in the AAB condition, and 2% in the BAA condition); while there were fewer cases in which the same–different pattern was correct but one or more of the letters was missed (13% in the ABA condition, 11% in the AAB condition, and none in the BAA condition). In the AAA condition there was not a single

case where S knew that all 3 letters were the same, but did not know what the letter was (an XXX error).

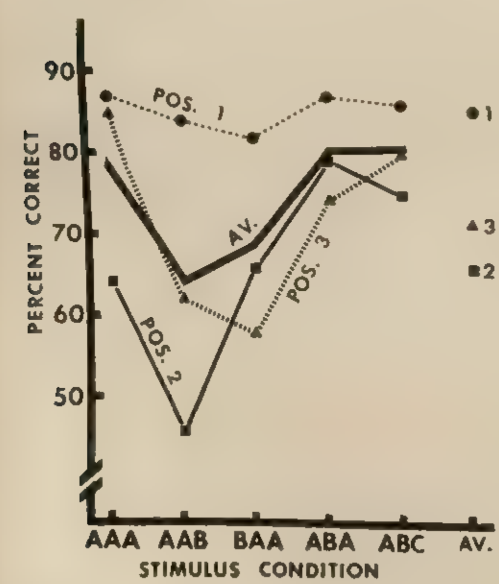

Figure 2. Percentage of letters correctly identified for each condition and position, Experiment II. (The A-B combinations represent the 5 same-different patterns. Av. = average.)

Experiment II

There were 2 major findings in Experiment I that could be viewed with some suspicion. First, the absence of a significant difference between the AAA and ABC conditions supports the null hypothesis, which is a questionable conclusion. Second, the poor performance of the AAB condition was so unexpected that it warranted replication.

Method

The design, equipment, and procedure of the second experiment were identical to those of Experiment I with the following differences: the stimuli were numbers instead of letters; there were a total of 40 stimuli instead of 50; Conditions AAA, ABA, and ABC each had 10 stimuli and Conditions AAB and BAA each had 5 stimuli; and only 10 *Ss* were used instead of 15.

Results

The results of Experiment II are shown in Figure 2. The 2 tenuous conclusions of Experiment I were firmly supported by these data. First, the performance of the AAB condition was inferior to the performances in the other conditions; and second,

there was little difference between the performances of the AAA and ABC conditions, this case the ABC condition was ior to the AAA condition. This difference is in the opposite direction from that licted from the Beller (1970) – Neisser 57) model. An analysis of variance indicated that both main effects of condition and position were significant at the .001 level and the interaction between them was significant at the .05 level: for conditions, $F(4, 126) = 5.36$, for position, $F(2, 126) = 15.63$, and for the interaction, $F(8, 126) = 2.05$. A Tukey test on the condition means averaged across positions indicated that the AAB condition differed from the ABC and ABA conditions at the .01 level and from the AAA condition at the .05 level. Another Tukey test on the position means averaged across conditions indicated that the first position performance differed from the other 2 at the .01 level.

Discussion

The most important conclusion of this research is that the recognition of AAA stimuli, in which all 3 letters were the same, and the ABC stimuli in which all 3 letters were different, did not differ significantly, and this was true with either numbers or letters as stimuli. It can be concluded from this finding that either the same–different pattern of the stimuli was not discerned before the letters were identified or that it was discerned but not used. The latter seems unlikely. If the same–different pattern had been detected prior to the letters being identified, then there should have been many more cases in the AAA condition in which *S*'s response had all 3 letters the same but used the wrong letter. This result calls into question Beller's (1970) assertion that physical sameness is detected by the preattentive mechanisms prior to identification.

However, it is still necessary to resolve the difference between Beller's (1970) data and the present data. Beller found that when *S*s were asked to make same–different judgments on the basis of name, response times were considerably faster when all stimuli were physically identical, and it took no longer to classify 8 physically identical stimuli as same than it did to classify 2. He concluded that physical match was done prior to the actual naming process and that it was done in parallel. The present study concluded exactly the opposite. However, there are some important differences between the task of Beller's *S*s and the task of the *S*s in the present experiments. Beller's *S*s were required to decide whether the letters presented had the same name or not. The actual task of naming was only implicit. In the above experiment, *S*s were required to actually say the names of the letters. Apparently this difference can produce important differences in processing strategies in the sense that certain preattentive processes seem to be optional. When *S*s are required to make a name match, i.e., say whether 2 or more letters have the same name or not, they apparently employ a preattentive mechanism which makes physical matches prior to actually naming the letters. However, when their only assignment is to name the letters, then they can somehow forgo the use of the matching mechanism. In other words, which preattentive mechanisms are employed seems to depend on the specific task.

A second finding of the present experiments is that recognition performance with AAB stimuli was considerably lower than performance in other conditions. This result is puzzling; perhaps some sort of symmetry notion can account for it; symmetry has been found to play a role in other perception experiments (e.g., Bryden, 1968), but this would require some stretching of the notion of symmetry. At present, this phenomenon will have to be left unexplained.

A third finding was that *S*s were much more likely to get the first letter correct than the other 2 letters. This finding is not surprising; it has been reported in other studies (Bryden, 1960). What it indicates is that *S*s are most probably reading from left to right, and it provides support for the notion that the letters are synthesized serially, one after the other, rather than in parallel (although the observation that *S*s often knew what letters were present without knowing their order suggests the opposite). However, a parallel processing model could also account for the position effect by postulating that since the letters are spoken in a left-to-right order, there is a greater chance that *S* will forget 1 of the last 2 letters rather than the first letter because he has to keep them in memory while he reports the first.

Finally, these experiments may be taken as a demonstration of a case where one type of meaning information can be extracted directly from a stimulus without first having to

attend to, recognize, or identify a lower and presumably more basic type of physical or sensory information. Other research suggests that *S*s are capable of performing in a similar manner with other types of information. For example, Brand (1971) reported that some *S*s were able to search through a list of letters more rapidly for "any number" than for a specified letter, suggesting that they are capable of determining whether a pattern is a number or a letter without first identifying it. This is not to say that basic sensory information is of no importance to perception, but rather that there is some sort of higher order invariant of "numberness" or "letterness" which can be detected independently of identifying any particular alphanumeric character. Similar notions have been expressed by Gibson (1966). In any event Brand's finding agrees with the present results in that it suggests that what is presumed to be higher order information can be extracted without first identifying lower order information. Thus, simple hierarchical models of pattern recognition in which lower level information is extracted first and then used to detect higher order features must be called into ... question.

ACQUISITION AND TRANSFER OF INTERCONTROL MOVEMENT DEPENDENCE IN TWO-DIMENSIONAL COMPENSATORY TRACKING[1]

RICHARD B. HOPPE[2]

University of Minnesota

Two experiments on the acquisition and transfer of dependent (D) and independent (I) interaxis control movement patterns are reported. Task dependence, defined as the correlation between the stimulus signal rate functions in the 2 axes, was varied in a transfer design. Twelve *Ss* in Experiment I and 24 *Ss* in Experiment II trained on either an I or a D task then were transferred to a test task with the same (Experiment I) or different (Experiment II) intraaxis characteristics, and the same (nonshift) or different (shift) interaxis dependence. Results showed the following: (*a*) *Ss* approached the dependence required by the task in training trials, (*b*) shift *Ss* had greater error increases in test than nonshift *Ss*, (*c*) *Ss* trained on an I task and tested on a D task (I–D *Ss*) showed greater relative negative transfer than D–I *Ss*, and (*d*) the fit of the multiplicative rule for time-on-target scores to observed data was not related to movement dependence or to movement simultaneity.

The principal objects of this research were (*a*) to ascertain the relationship between the 2-hand movement dependence exhibited by *Ss* on a 2-dimensional tracking task and the fit of the multiplicative rule for time-on-target (TOT) scores, and (*b*) to determine whether the interlimb movement dependence required by the task is necessary to an adequate description of what *Ss* learn in tracking. The multiplicative rule for TOT scores is an empirical relationship between the product of part-task scores and observed whole-task performance. Ellson (1947) first noted that the proportions of TOT in each of the dimensions of a multidimensional task appeared to be statistically independent, so that

$$P(\mathrm{TOT}_{abc}) = P(\mathrm{TOT}_a) \times P(\mathrm{TOT}_b) \times P(\mathrm{TOT}_c), \quad [1]$$

where $P(\mathrm{TOT}_{abc})$ is the proportion of time that *S* was on target in all 3 dimensions simultaneously, and $P(\mathrm{TOT}_a)$, $P(\mathrm{TOT}_b)$, and $P(\mathrm{TOT}_c)$ are the proportions of TOT in each of the 3 part tasks measured without regard to each other. This rule has been shown to be very powerful. In a variety of tracking tasks, both pursuit and compensatory, and for various stages of practice, the rule predicts observed simultaneous $P(\mathrm{TOT})$ within approximately 2% (Adams & Webber, 1961; Bilodeau, 1955, 1957; Bilodeau & Bilodeau, 1954; Dick, 1970). The rule is robust over target sizes (Adams & Webber, 1961), at least under certain circumstances, and for up to 4-dimensional tasks (Bilodeau, 1957). As an empirical law relating part-task scores to whole-task performance in terms of system error, the multiplicative rule is unrivaled in its precision and range.

The question at issue is whether the operation of the multiplicative rule implies that the behavior giving rise to the TOT scores is somehow independent in the

several control dimensions. This implication is based on the similarity of the form of the multiplicative rule to the equation defining the joint probability of independent events. Adams and Webber (1961) explicitly presumed this to be the case when they said,

> Therefore, at present, we have no evidence to contradict the independence law [multiplicative rule] and must accept it as a first quantitative principle of complex tracking *behavior* with no known restrictions on task, practice, or characteristics of the input signals [p. 200, italics added].

Other investigators have been more aware of the difficulty of inferring behavioral conclusions from TOT error data. In their discussion of an experiment in which the data were well-predicted by the multiplicative rule, Bilodeau and Bilodeau (1954) said,

> To conclude from these data that the relation [between *P*(TOT) scores] is essentially zero, for example, is not necessarily to conclude that manipulative corrections between components are always independently performed [p. 42].

Nevertheless, they went on to say that "over a sizable time interval the events [manipulative corrections] can on the whole be considered to be independent [p. 42]," this conclusion being based on *P*(TOT) data.

The principal difficulty with these kinds of inferences is the meaning to be assigned to "independence" as it refers to behavior and to response patterns. The term has taken several meanings in the literature. Perhaps the most commonly encountered meaning identifies the degree of independence (or dependence) with time-sharing patterns across control dimensions. If *S* moves 2 controls in an alternating manner, he is displaying little time-sharing; if he tends to move the controls simultaneously, he is displaying increased time-sharing. This definition of independence is apparently assumed in the Bilodeau and Bilodeau (1954) quotations above, though, as noted, they depend upon TOT error data for their premises. The term has taken other meanings. For example, Adams and Webber (1961), also quoted above, defined behavioral independence in terms of cross-correlation functions relating tracking error signals in 2 dimensions of tracking. A misconception underlying these definitions is that tracking error is a valid index of *S*'s responding on the task. As both Dick (1970) and Hoppe (1972) have pointed out, tracking error confounds the system forcing function and *S*'s responses. As a consequence, without an adequate description of the forcing function it is impossible to separate their effects. Error indices are measures of system performance, not human responding, and without a behaviorally relevant description of the task set for *S* it is not possible to meaningfully assess his responding based upon error data.

Dick's (1970) major contribution was to (correctly) observe that conclusions about human responding in a tracking system must be based upon indices that are unambiguously descriptive of that responding. Accordingly, Dick performed his major analyses on the recorded output of *S*s' control manipulanda. While Dick's insight was notable, there is one more indispensable prerequisite to an experimental methodology adequate for the study of human skilled behavior. In order to be interpretable, any measure must have a referent. The referent for measures of tracking error is zero system error. The referent for measures of tracking behavior is not so obvious. It is what Hoppe (1972) has called the reference response pattern (RRP). The RRP is the precise spatiotemporal pattern of control movements necessary to produce zero system error through the length of a trial. The RRP derives from a reconceptualization of *S*s' task as a behavior-reproduction task, at least for the purposes of measurement, and serves the same purpose as the zero error referent for the error measures. (The RRP is developed in more detail in Hoppe, 1972.) The assumption of zero error as the criterion system performance implies that *E* should use indices of deviation from zero system error as dependent variables. The assumption of the RRP as the criterion behavior patterning implies that *E* should use indices that reflect deviations from that pattern as dependent variables. The

two are not mutually exclusive, but are complementa

As a consequence, a prerequisite for tracking research is a specification of the task requirements in the same terms to be used to describe Ss' behavior. Since the present research deals with response dependence, it is necessary to define dependence in a way that renders it quantifiable and experimentally manipulable. In this research, dependence is defined as the relationship of the rate and direction of control movement in one axis to the rate and direction of movement in the other axis. More precisely, interaxis movement dependence in a 2-dimensional tracking task is indexed by the product-moment correlation of the rate functions in the 2 axes, the 2 rate functions being synchronized in time. This correlation is the dependence coefficient (DC) and is an index of what kind of movements of one control go with what kind of movements of the other control.

consider a 2-dimensional task in which S controls Dimension A by pushing lling a control rod with his right hand. l controls Dimension B by l-grip handle held in his he definition above, S is splaying dependent responding when the DC derived from his response movements departs from zero. This is equivalent to saying that S is moving in a dependent manner when, e.g., a clockwise twist of the left-hand control is statistically associated with pushing on the right-hand control. (Zero dependence does not mean that S is not moving both controls continuously and/or simultaneously, but only that there is no statistical association of the rates and directions of movement of the 2 controls.) The sign of DC reflects the particular association; in the research reported in this article, a negative DC indicated an association of counterclockwise twisting with pushing and clockwise twisting with pulling. One question addressed by the research reported here is whether task dependence so defined, when varied, produces concomitant variation in the fit of the multiplicative rule to Ss' error data.

The second and more general question addressed is whether dependence so defined is part of what Ss learn when practicing a tracking task. Textbook accounts of skills learning typically refer to the integration of part skills, or to the spatiotemporal patterning of movements (see, e.g., Fitts & Posner, 1967; Kay, 1969; O'Donnell, 1969), but there are few experimental data which give these assertions more than intuitively based meaning. In characterizing the task in the same terms to be used to describe Ss' behavior in multidimensional tracking, the present research aims to provide the beginning of an empirical substrate for an account of learning of complex psychomotor skills.

Experiments I and II

Two experiments were performed to assess the effects of varying the DC task on (a) overall system performance, indexed by root mean square (rms) error, (b) the goodness of fit of the multiplicative rule to Ss' data, and (c) the degree of interaxis control movement dependence displayed by Ss. The experiments were similar in general form and will therefore be described together. Since the effort in the experiments was to determine the importance of task dependence to a description of what S has learned, a transfer design was used; Ss were trained on one task dependence and tested on another. In this manner it was hoped to ascertain whether Ss were merely coming to display the interaxis control dependence required by the task, or were in fact learning something about that dependence that has effects on subsequent responding on a task with a different DC. During training on a dependent (D) task, the DC of Ss' responding is expected to approximate, over trials of practice, the DC defined as criterion by the system forcing functions. This would demonstrate that Ss can impose a D structure on their responding if the task requires it. Transfer to an independent (I) task is expected to show, by comparison with an appropriate control, whether the D response patterning is a learning or performance variable. It is possible that Ss in a D task are learning to

respond appropriately in the 2 axes simultaneously, but are not learning the dependence between responses in the 2 axes. If these *S*s are shifted to an I task that is identical to the D task except for the dependence between axes, *S*s' DC should shift immediately to the test task value, and the system performance measure should show no change as a function of the change in tasks. The same prediction would hold for *S*s trained on an I task and tested on a D task. If, on the other hand, there is an effect due to the shift in tasks, then one may conclude that *S*s were learning the dependence of responding in the 2 axes.

The experiments were also designed to assess the relationship between the multiplicative rule for TOT scores and behavioral independence/dependence. If the rule is in fact an index of behavioral independence as defined by DC, then it is to be expected that it will differentiate between *S*s trained on tasks having different DCs. Specifically, the rule should predict the *P*(TOT) scores of *S*s performing on an I task better than the scores of those performing on a D task. If there is no regular relationship between behavioral dependence and the rule's predictions, then one may conclude that the rule is not an indicant of independent responding on the 2 controls.

The general approach in the experiments was to train *S*s on a 2-dimensional compensatory tracking task with a known, *E*-determined DC. The *S*s were then transferred to a task with either identical (Experiment I) or different (Experiment II) intraaxis characteristics, and the same (nonshift groups) or different (shift groups) interaxis control movement dependence. The experiments were full transfer designs, with all 4 groups (I–I, D–D, I–D, and D–I) run in both.

Method

Subjects. The *S*s were 36 right-handed male undergraduate students in introductory psychology classes at the University of Minnesota. Experiment I used 12 *S*s, and Experiment II used 24 *S*s; all *S*s were volunteers who received extra class credit for their participation.

Apparatus. A multidimensional compensatory tracking system, the Minnesota Tracking System (MTS), was used. For both experiments, the MTS was wired as a 2-dimensional system. Error information was displayed to *S*s in the form of a dot of light moving in 2 orthogonal dimensions on an 8 × 10 cm. oscilloscope screen. The *S*s controlled the movement of the dot in the vertical dimension by pushing and pulling a control rod with the right hand; pushing the rod moved the dot upward on the display, pulling moved the dot downward. Control in the horizontal dimension was accomplished by twisting a pistol-grip handle held in the left hand; twisting the control clockwise moved the dot to the right on the display, twisting counterclockwise moved the dot to the left. The range of travel of the right-hand push–pull control was 40 cm., corresponding to 11 cm. of vertical displacement of the dot, ±5½ cm. from the center of the display face. Control–display gain in the vertical dimension was 3.64:1.0. The range of travel of the left-hand twist control was 160°, corresponding to 11 cm. of horizontal displacement of the dot, ±5½ cm. from the center of the display face. Control–display gain in the horizontal dimension was 14.55:1.0. As is obvious, both controls were capable of moving the dot completely off the 8 × 10 cm. display face. The center of the display was indicated by the intersection of 2 hairlines; the centers of the ranges of both controls corresponded to this cross-hair-defined center. The MTS is described in detail by Dick (1970).

System forcing functions. Since the composition of the system forcing functions is critical to the experiments, it is necessary to describe them in some detail. In Experiment I, 2 pairs of forcing functions were used. Each pair consisted of 2 complex signals, 1 for the vertical dimension (A axis) and 1 for the horizontal dimension (B axis). All of the complex signals in both pairs were formed by combining a 5-cpm function with a 12-cpm function in the following manner. In the A axis, the complex signal was the resultant of the combination of a 5-cpm sine function with a 12-cpm sine function. The peak-to-peak amplitudes of the 2 functions were equal. In the B axis, the complex signal was the resultant of the combination of a 5-cpm sine function with a 12-cpm negative cosine function, again with the peak-to-peak amplitudes of the component functions equal. The 2 D conditions used in Experiment I were obtained by varying the interaxis phase relationship between the 2 complex signals to obtain the desired value of DC. A value of DC = 0.0 was the I stimulus, and DC = −.70 was the D stimulus. The result of these manipulations was one set of 5- and 12-cpm stimuli for the D experimental condition, and another set of 5- and 12-cpm stimuli for the I experimental condition. Since the period of the complex functions used in each axis is 60 sec., *S*s in both conditions saw 1 complete cycle of each stimulus signal within each trial. The only difference between the I and D conditions was the point in the cycle where the B axis began. In the D condition, a clockwise twist of the left-hand control was associated with pulling the right-hand control, and a counterclockwise twist was associated with

pu[illegible] the right-hand control. As the value of [illegible] for DC in the D condition indicates, the association was not perfect, but was a partial dependence. In the I condition there was no systematic relationship between the control movements required in the 2 dimensions.

The stimuli for Experiment II were generated in the same manner as in Experiment I, except that in addition to 2 sets of 5- and 12-cpm combinations, 2 sets of complex functions composed of 6- and 10-cpm sine functions were generated. The latter had the same dependence relationships as the 5- and 12-cpm signals, and the same peak-to-peak amplitudes. In Experiment II, the 2 sets (I and D) of 6- and 10-cpm signals were used as training stimuli, and the 2 sets of 5- and 12-cpm signals were used as test stimuli. In Experiment I, the same 2 sets of 5- and 12-cpm signals were used in both the training and test phases. All trials within each set of stimulus conditions were identical. All the forcing functions had peak-to-peak amplitudes sufficient to drive the dot ±4 cm. from the center of the display in both dimensions.

Procedure. The basic design of the experiments is shown in Table 1. Half of the *Ss* in each experiment were randomly assigned to the D training condition and half to the I training condition. At the end of the training phase, the training groups in Experiments I and II were randomly reassigned, half of each being tested on a task with the same (I or D) DC as in training and the other half on a dependence different from the training DC. This procedure yielded 4 groups in the test phases of Experiments I and II: I–I, D–D, I–D, and D–I.

The *Ss* were trained for 24 1-min. trials on the appropriate task, and then were shifted to their respective test tasks for 16 1-min. trials. Trials were presented in blocks of 8, the intertrial interval being 30 sec., and the interblock interval, 5 min. The *Ss* left the experimental room during the interblock interval while *E* prepared the next block of trials. The shift at transfer was made during the normal interblock interval, between the third and fourth blocks, and *Ss* were not informed of the change.

Instructions to *Ss* told them only that the experiment dealt with human motor skills, and that their task was to keep the dot centered on the screen by appropriate manipulations of the controls. The *Ss* were given a short pretraining familiarization with the action of the controls in the absence of a forcing function and then received their training and test trials in one experimental session. The *Ss* were aware that data were continuously recorded, but were not informed of the nature of the analyses to be performed. No feedback other than that present on the display during the course of a trial was given; nevertheless, *Ss* appeared to be well motivated and, without exception, were cooperative.

Measurement. The 2 response signals generated by *Ss*' manipulations of the controls and the forcing functions driving the dot in the 2 dimensions were simultaneously tape recorded for all trials. In the computer analyses, the 4 signals were simultaneously

sampled and converted to digital values at a 10-Hz. rate, and all analyses were performed on the digitized data. The sampling rate of 10 Hz. is sufficiently higher than the rates present in the sampled signals to assure good digital approximations to the original continuous signals. Using the digitized data, the following 4 measures of various aspects of *Ss*' responding and of system performance were calculated: rms error, DC, simultaneity index (SI), and an index of the goodness of fit of the multiplicative rule's prediction to the observed data. A brief description of the measures follows.

1. The rms error is the square root of the mean square tracking error over a trial. For each trial, each *S* has an rms error score for each dimension of the task. To derive error values from the recorded data required only that the computer calculate the difference between the amplitude of the forcing function in a given dimension and the amplitude of the response signal in that dimension at each sample point. These error values formed the basis for the rms error scores. The rms error is a sensitive, reliable measure of system performance (Bahrick, Fitts, & Briggs, 1957; Kelley, 1969). Decreasing rms error indicates increasingly good system performance. In addition, in a zero-order control system like the MTS, rms error is an index of the overall approximation of *Ss*' control position to the criterion control position.

2. The DC is the product-moment correlation of the rate-of-change in one axis with the rate-of-change in the other axis. The DC of the forcing functions is the criterion dependence required for perfect performance; the DC of *S*'s responding in the 2 axes is the dependent variable.

3. The SI is the ratio of simultaneous movements and nonmovements to the total number of sample periods, and is an index of output (response) time-sharing. Given a 4-fold table of movement (M) and nonmovement (NM) in Dimension A vs. M and NM in Dimension B, the M/A, M/B intersection is Cell A, the M/A, NM/B intersection is Cell B, the NM/A, NM/B intersection is Cell C, and the NM/A, M/B intersection is Cell D. For each 100-msec. sample interval during a trial, the computer decided whether *S* moved both controls, moved one control but not the other, or did not move either control. A movement was defined as a change in

the amplitude of the response signal of greater than 10 mv., which corresponds to a movement rate of .51 cm/sec on the vertical control and 3.16 degrees/sec on the horizontal control. For each sample interval the computer makes an entry in the appropriate cell of the table. At the end of a trial, SI is calculated as follows:

$$\mathrm{SI} = \frac{A + C}{A + B + C + D} \qquad [2]$$

The SI of the forcing functions used in Experiments I and II was approximately .80, which is the criterion value defined by the task. The SI of *S*s' responses is the dependent variable. It should be noted that because of the definition of very low rates as NMs, Cells B and D will be slightly inflated and as a consequence SI artifactually underestimates the actual simultaneity of the task and of *S*s. However, since both the task criterion SI and the SI of *S*s are underestimated to the same degree, the relation of the two is meaningful. (Cell C is also slightly inflated for the same reason, but since it appears in both the numerator and denominator of Equation 2 this does not affect the ratio.)

4. The method of determining the $P(\mathrm{TOT})$ scores from which to evaluate the goodness of fit of the multiplicative rule is somewhat out of the ordinary, and must be described in some detail. Bahrick et al. (1957) noted that the target size most sensitive to variations in system performance is one which encompasses approximately 68% of the error amplitude distribution. Since error in a tracking task varies as a function of practice, a given fixed target size will be more or less sensitive at various stages of practice. Therefore, for each *S*, the target size used was set equal to ±1 rms in each axis for each trial. This variable target was used to compute $P(\mathrm{TOT_a})$, $P(\mathrm{TOT_b})$, and $P(\mathrm{TOT_{ab}})$ for that trial in a post hoc analysis. This procedure results in fairly constant $P(\mathrm{TOT})$ scores for each individual axis and for the product of the single-axis scores, which is the prediction of the multiplicative rule. This technique of using post hoc target sizes based upon the dispersion of *S*'s own error amplitude distribution is due to Dick (1970). The goodness of fit index is then:

$$\text{Goodness of fit} = [P(\mathrm{TOT_a}) \times P(\mathrm{TOT_b}) - P(\mathrm{TOT_{ab}})] \times 100, \qquad [3]$$

where $P(\mathrm{TOT_a})$ and $P(\mathrm{TOT_b})$ are the proportions of TOT in each dimension, and $P(\mathrm{TOT_{ab}})$ is the proportion of TOT in both dimensions simultaneously. Assuming that mean tracking error is approximately zero and that the error amplitude distribution over a trial is approximately normal (Bahrick et al., 1957), then 1.0 rms ≐ 1.0 *SD* of the error amplitude distribution. From this it follows that the approximate range of the index is from −22% (maximum possible underestimation) to 10% (maximum possible overestimation).

In all the data analyses, only the middle 50 sec. of each trial were included. The first and last 5 sec. of each trial were dropped to avoid target acquisition artifacts and, at the end of a trial, the possibility of a synchronization error that would i[illegible] a few samples of posttrial noise from the tape containing the raw data. As a consequence, the values of DC defining the I and D conditions in the experiments were not precisely 0.00 and −.70 as originally planned, but varied slightly. In Experim[illegible]I, the D stimuli (both test and training) D[illegible].68, the I stimuli (test and training) DC = .0[illegible] In Experiment II, the D training stimuli D[illegible].66, the D test stimuli DC = −.71, the I train[illegible]timuli DC = .02, and the I test stimuli DC [illegible] The differences between the I and the D D[illegible]ppear to be negligible.

Results

This section focuses primarily on the results of Experiment II. With respect to the task dependence variable, the 2 experiments are replicates, so the results of Experiment I will be introduced only as necessary to support the Experiment II data. In general, the Experiment I results parallel those of Experiment II.

System performance. The measure of system performance, rms error, showed clear change as a function of practice and as a function of the change in dependence at the shift between Blocks 3 and 4. It decreased over trials of training, approaching asymptotic levels in the second and third blocks of training in both experiments. The I group tended to have slightly higher error through the training trials. In Experiment II, at the shift between Blocks 3 and 4, all 4 test groups showed an increase in system error. This in itself is not surprising, since the test-task forcing functions contained both higher and lower rates than the training forcing functions. However, the shift groups (I–D and D–I) showed greater increases from Block 3 to Block 4 than did the nonshift groups. Table 2 shows the ratio of rms error in Block 4 over rms error in Block 3 for the 4 test groups. Each entry in the table is the mean rms error in Block 4 of one of the test groups divided by the Block 3 mean rms error for the 6 *S*s of that test group. All of the ratios are greater than 1.0, indicating that system error increased as a function of the task change in all 4 groups. Also apparent in the table is a pattern reflecting

fects of the changed dependence for shift groups. They show greater increase in rms error than the nonshift groups. There was an increase in system error due to the change in task dependence over and above that due to the change in the intra-axis characteristics of the task. The Experiment I data showed the same general pattern. With the exception of 1 *S* in the I–I group, the nonshift groups improved (i.e., ratios < 1.0), which is reasonable since in Experiment I their tasks were identical in training and test. The shift groups, on the other hand, showed increases in system error from training to test. These increases can only be due to the change in dependence, since the intra-axis characteristics of the training and test tasks were identical in Experiment I. This result was consistent at the individual *S* level. In Experiment I at this level there are 24 ratios (12 *S*s $\times$ 2 variables), and of these 24 ratios only 3 depart from the pattern described. Of the shift *S*s' ratios, 11 of 12 were greater than 1.0; of the nonshift ratios, 10 of 12 were less than 1.0.

A transfer analysis comparing shift groups with nonshift controls, using Briggs' (1969) Equation 1, was performed on the Block 4 rms error data.[3] This transfer index is:

$$\frac{\text{Control group} - \text{Experimental group}}{\text{Control group}} \times 100. \quad [4]$$

For rms error, which decreases with improved system performance, the index varies from 100% to minus infinity. Table 3 presents the transfer indices calculated from the Block 4 mean rms error data of Experiment II. All of the indices have negative signs, indicating greater rms error in the shift groups. In addition, the I–D group showed greater negative transfer than the D–I group. Again, the Experiment I data replicate the pattern of Table 3, showing general negative transfer (with the exception of 1 aberrant *S*), and differentiating the D–I from the I–D group, in spite of the aberrant *S*. The transfer indices, together with the ratios of Table 2, show that there was a detrimental effect on system performance due to the change in task dependence at transfer.

Fit of the multiplicative rule. The multiplicative rule generally predicted observed *P*(TOT) very well in both experiments. The range of the block mean goodness of fit indices varied over less than 10% of the total possible range of the index. The rule generally underestimated observed *P*(TOT), and at the block mean level of analysis appeared to segregate groups by task dependence, the D groups being underestimated more than the I groups in both training and test blocks. Both experiments produced the same patterns of results in these respects.

However, the goodness of fit data were not as regular as the block means imply. Figure 1 shows the goodness of fit index over the last 8 training trials and the first

[3] The terms in the numerator of Equation 4 are reversed from Briggs (1969) so as to yield negative transfer indices in those cases where the experimental group error was greater than the control group error. Relative to a (hypothetical) control group receiving no training prior to the test trials, of course, all test groups showed positive transfer.

TRANSFER INDICES COMPARING ROOT MEAN SQUARE (RMS) ERROR OF SHIFT GROUPS WITH RMS ERROR OF NONSHIFT CONTROL GROUPS: EXPERIMENT II, BLOCK 4 MEAN DATA

Condition	Dimension A	Dimension B
Independent–dependent	−18.7%	−16.4%
Dependent–independent	− 7.4%	− 6.3%

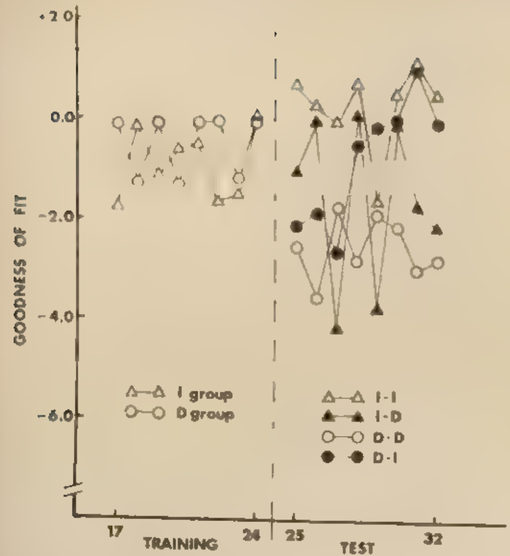

FIGURE 1. Goodness of fit of the multiplicative rule over the last 8 training trials (Block 3) and first 8 test trials (Block 4) of Experiment II. (Abbreviations: I = independent, D = dependent.)

8 test trials of Experiment II. As is obvious, the fit of the rule to the data was neither regular nor clearly related to task dependence. (Block 3 of Experiment II was the only place where the D and I *Ss* were not separated at the block mean level of analysis.) There is considerable overlap of the trial mean goodness of fit in the various test groups, and it is not the case that the fit of the multiplicative rule is unequivocally determined by the task dependence, where dependence is defined in terms of DC. Again, the Experiment I data agree.

Behavioral dependence. The interaxis response dependence displayed by *Ss*, indexed by DC, is shown over the 40 trials of Experiment II in Figure 2. (The DC data are in the form of logarithmic transformations of *r*. This transformation was performed for purposes of analyses not germane to the present discussion, and does not affect the results reported here.) As the figure shows, *Ss*' interaxis control movement dependence changed as a function of practice, and the change is in the direction of the task-required dependence. The training-trial means approach the criterion dependence in both conditions, the D *Ss* moving in a more dependent manner and the I *Ss* moving more independently, but in neither condition did they reach the criterion in training.

The change in DC at the shift appears to be quite regular. The D–D group increases DC slightly, corresponding to the slight increase in task dependence, and the I–I *Ss* change DC slightly in a positive direction, again corresponding to a small change in the task dependence. The shift groups (I–D and D–I) also change dependence rapidly. The I–D group, while quickly changing dependence at the shift, does not change to the value of the D–D control group, but falls short by a small margin. In Block 3, the D–D group block mean was at 79.7% of the criterion value, while in Block 4 it was at 79.5% of the criterion. That is, there was no substantial change in the D–D *Ss*' relationship to the task criterion DC as a result of the change from a dependent 6- and 10-cpm task to an equally dependent 5- and 12-cpm task. The I–D group, however, reached only 70.5% of the criterion dependence in the first test block. This pattern of results was replicated in Experiment I, where the D–D *Ss* were at 94.0% of criterion in Block 3 and 95.2% in Block 4, while the I–D group reached only 73.5% of criterion in Block 4. The I–D trial means are consistently below those of the D–D *Ss* through Block 4 in both experiments. A 2-way analysis of variance with repeated measures on one

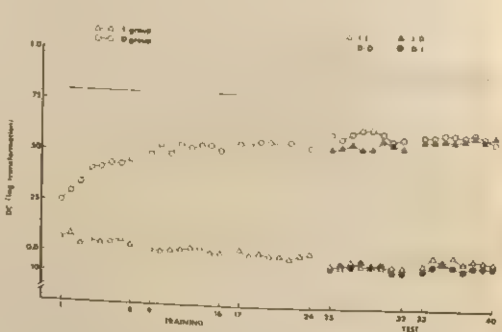

FIGURE 2. Mean dependence coefficient (DC) over the 40 training trials of Experiment II. (The horizontal bars over the data points indicate the task criteria DC for the dependent [D] group; the independent [I] group criteria were .02 in training and .04 in test.)

ctor (trials) was used to assess the tatistical significance of the effect of training dependence (I or D) on the DC of *S*s' responding on a D task in Block 4 of Experiment II. Neither the training dependence main effect, F (1, 10) = 2.18, the trials main effect, F (7, 70) = .60, nor the Training Dependence × Trials interaction, F (7, 70) = .67, was statistically significant. However, the replicability of the phenomenon renders the nonsignificant outcome of a statistical inference based on one set of data less than compelling.[4]

The shift in dependence from D to I showed no effects like those just described. The D–I *S*s shifted directly to the new dependence at transfer, and were indistinguishable from the I–I controls at both the block and trial mean levels of analysis. This result also replicated in Experiment I and in the partial replication mentioned in Footnote 4. In general, the results of the DC analyses show that while training on a D task has no discernible effects on the dependence displayed on a subsequent I task, the reverse is not true. Training on an I task is not equivalent to training on a D task with respect to subsequent responding on a D test task. This asymmetry is reflected in the rms error transfer indices in which the I–D groups show greater negative transfer than the D–I groups in both experiments. The greater negative transfer in the I–D groups' system error may be due to the failure to move in as dependent a manner as the D–D control groups in Block 4. This is not to say that there is *no* commonality of what is learned in the 2 tasks; it is obvious that *S*s in both training conditions are learning very similar skills, but they are also learning something different: a relationship in the D condition between particular movements of one control

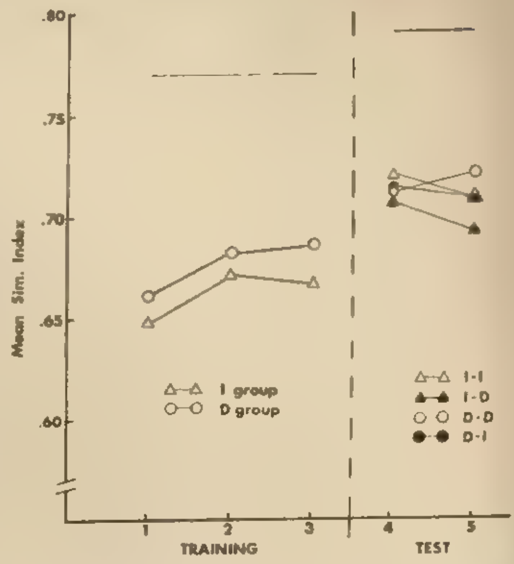

FIGURE 3. Simultaneity index (SI) over blocks of 8 training and test trials of Experiment II. (Horizontal bars over data points indicate training and test SI criteria. Abbreviations: I = independent, D = dependent.)

and the other control which did not characterize the I condition.

The SI is shown over blocks of trials of Experiment II in Figure 3. Note the expanded scale on the vertical axis of the figure. The total possible range of the index is 0.0–1.0; the vertical axis includes only 20% of this range. In terms of the total range of the index, SI changed very little as a function of practice. Although the task SI was not a manipulated variable in the experiments, it did change slightly in Experiment II, increasing from .77 to .79 with the shift in tasks at transfer. The *S*s' SI changed abruptly at the shift, paralleling the change in criterion SI. In training there appeared to be a segregation of the groups by task dependence, but it did not remain consistent in the test blocks, even for the nonshift groups. The Experiment I data replicated the Experiment II results in that in training, D *S*s exhibited a slightly higher SI than I *S*s, while in test the groups were not differentiated according to task dependence. Both training conditions within each experiment had the same criterion SI, and the author has no

---

[4] It is worth noting that a third partial replication, in which 2 groups of 3 *S*s each were trained on 6- and 10-cpm I and D tasks and then shifted to the other (D or I) dependence, yielded results (compared to extrapolations of training data) showing the same patterns of transfer asymmetry as the 2 full experiments reported here. The fact that the patterns replicated 3 times is sufficiently strong evidence to show that they did not occur by chance.

satisfactory explanation for the separation in training.

The SI does not appear to be clearly related to the fit of the multiplicative rule to Ss' data. While the SI data indicated a consistent differentiation between dependence groups in training, the multiplicative rule's fit to their $P(TOT)$ data varied considerably. Changes in the goodness of fit of the rule did not reflect changes in response time-sharing patterns.

Discussion

It was noted in the Results section that the fit of the multiplicative rule was not determined by task dependence, but there was no particular reason to suppose that it would be. The rule has been taken to be an indicant of *response* independence, an index of the degree to which Ss' responses in one component of the task are independent of those in the other component. It is clear by now that the rule is not directly related to response dependence whether dependence is defined as movement simultaneity (SI) or as the correlation between the rates of movement of the 2 controls (DC). The training data of Experiment II provide sufficient reason to reject both interpretations of the rule: While the rule's predictions were becoming more accurate over training blocks, the D and I group means becoming almost identical in this respect, both DC and SI clearly differentiated Ss in the 2 conditions. As a consequence, it must be concluded that the multiplicative rule for TOT scores, while a powerful empirical relationship between system performance component measures, does not reflect an underlying behavioral independence. The SI training data suggest that a D track, in which there is statistical predictability from one control to the other, tends to encourage response time-sharing, but the test data for the I I and D D groups do not bear this out.

The data indicate that Ss can and do impose a dependent structure on their responding when the task situation requires it. On the other hand, if the task requires independent movements, Ss can supply them. Given trials of practice, Ss approach the dependence defined by the task as criterion. Over and above this, it appears that task dependence may be part of what Ss learn in the practice trials. The relationship of the rms error transfer indices to the asymmetry of the DC shifts suggests that the I–D group had not learned everyt ng there was to know about responding on e D test task despite the intraaxis similarit f the 2 conditions in Experiment I. The rep tion of this pattern in Experiment II in face of a concomitant change in the intra characteristics of the task implies that I–D Ss must learn the dependent res patterning required by the new task. D–I Ss changed dependence immediately transfer, implying that they had acquired skill necessary to pattern their movem independently prior to the test trials, tho one should note that their rms error scores creased from training to test. It is not cert that this skill was acquired in the context the experimental training; it is possible that was acquired preexperimentally. There ma be population stereotypes regarding the inte limb patterning of movements in multidimen sional tasks. Research to explore this question is currently in progress.

The present research is the first in which question of human tracking behavior has bee explicitly studied in the light of the behavior requirements of the task. The view taken ha been that tracking is a behavior reproductio task. The S's job, from E's point of view, to reproduce the RRP defined by the syster forcing functions and the electromechanic characteristics of the control system. In ord to study behavioral dependence, it is necessary to specify the dependence required by the task and to evaluate Ss' responding with reference to this criterion. This approach would have led Dick (1970) to specify the phi correlation required by his task, as was done for SI and DC in the present research, so that the shifts in time-sharing he observed would have been interpretable. Similarly, Adams and Webber (1961), in attempting to ascertain the relationship between behavioral independence and the multiplicative rule, cross correlated error records. They found time lagged correlations that were reliably nonzero, and concluded that there was underlying behavioral dependence in spite of the fit of the multiplicative rule's predictions. However, Adams and Webber give no information regarding the task requirements in this respect beyond saying that they used "input signals that were . . . unsystematic between component tasks [p. 203]." Whether "unsystematic" means that the cross-correlation function relating the forcing functions in the 2 axes of their task did not depart from zero is unknown. The information necessary to interpret the data

reported is unavailable, and one cannot know just what the *Ss* were doing relative to the task requirements.

The research reported in this article supports the utility of the view of tracking, for measurement purposes, as a behavior-reproduction task. This view assumes that one's task as an experimental psychologist is to produce research answers to theoretical questions. Given that theories in psychology make predictions about behavior, it is logically necessary to have a research and measurement methodology capable of generating answers phrased in terms of behavior. It follows that the experimental task used must be described in terms of behavior, and the measures used must refer unambiguously to behavior. Thus the view of tracking as a behavior-reproduction task is not a theory of motor behavior, but is the basis for a research methodology appropriate to the study of that behavior.

CROSS-TASK VALIDATION OF FUNCTIONAL MEASUREMENT USING JUDGMENTS OF TOTAL MAGNITUDE[1]

NORMAN H. ANDERSON[2]

University of California, San Diego

The *Ss* rated total magnitude of 5 kinds of stimulus pairs: length length, area area, length area, length weight, and area weight. An adding model fit the data in each case, providing a within-task test of consistency. Functional measurement scale values for each dimension were linearly related across tasks, providing a between-task test of consistency. These 2 kinds of consistency tests validate the rating response as an interval scale of subjective magnitude, lending further support to previous conclusions that magnitude estimation is biased and invalid.

A perennial idea over the last 4 decades of work on psychophysical scaling has been the use of one or another algebraic model as a basis for measurement (see Anderson, in press-a, in press-b). Ratio models for fractionation and adding models for stimulus summation are examples. Such models impose a criterion of internal consistency on the data thereby constituting a validational base for the scales. Psychophysical data, however, have not generally fulfilled such criteria.

Magnitude estimation deserves particular note because of its widespread use. It is well known, however, that magnitude estimation data have not generally satisfied criteria of internal consistency (see, e.g., Anderson, 1970b, in press-a; Garner & Creelman, 1967; Poulton, 1968). Without such a validational base, magnitude estimation can be considered no more than an ordinal scale.

Recent developments show more promise. Functional measurement methodology (Anderson, 1970b), and related techniques developed by other investigators, begun to yield results that do show ternal consistency. This approach r heavily on the use of algebraic models psychophysical integration. The inte tion model serves as a scaling frame which to construct interval scales for stin lus and for response. Scaling then beco an organic part of substantive inquiry, a separate methodological preliminary.

An important outcome of this work is the support for ordinary rating methods. With modest experimental care, ratings can yield responses that are on an interval scale. Magnitude estimation, in contrast, seems to be biased and nonlinear (e.g., Anderson, 1972a; Weiss, 1972), a conclusion that is also suggested by the work of the Oregonians (e.g., Beck & Shaw, 1968; Curtis, Attneave, & Harrington, 1968; Curtis & Fox, 1969; Fagot & Stewart, 1969).

This report takes up an interesting task introduced by Feldman and Baird (1971) who asked *Ss* to judge "total intensity" of a sound plus a light. This kind of stimulus integration seems to call for an adding model. The adding model constitutes a criterion of internal consistency, and its success would allow construction of interval scales of the stimuli using functional measurement.

The total magnitude task also provides a criterion of cross-task consistency. Since *Ss* seem able to add stimuli from quite different modalities, diverse physical dimensions can be scaled under directly comparable conditions. Cross-task consistency

I wish to thank Holly Halvorson for research assistance, Michael Birnbaum for helpful comments on the manuscript, and Dwight Curtis and Stanley Rule for making available data and information cited in the text, and for comments on a draft of this paper.

[2] Requests for reprints should be sent to Norman H. Anderson, Department of Psychology, University of California, La Jolla, California 92037.

(Weiss & Anderson, 1969) requires that the scales for any one dimension should be the same across the different pairs in which it occurs. The present article gives an initial application of functional measurement methodology to this total magnitude task.

Method

Stimuli

The 3 sets of stimuli were length, area, and weight, with 5 stimulus levels in each set. The *lengths* ranged 4–20 cm. in 4-cm. steps. They were constructed of black drafting tape, 2-mm. wide, stuck to a white tagboard approximately 8 × 28 cm. The *areas* were circles with diameters ranging 2–6 cm. in 1-cm. steps. They were constructed of black paper, pasted on white tagboard approximately 10 × 14 cm. The *weights* ranged 200–600 gm. in 100-gm. steps. They were not visible, and were lifted by pulling down on a handle-pulley arrangement used in previous work (Anderson, 1972a).

The *S*s judged stimulus pairs, of which there were 5 types. Three were heteromodal (length–area, length–weight, and area–weight) and 2 were homomodal (length–length and area–area). The weight–weight condition was omitted as it would have involved serial rather than simultaneous presentation. The 3 heteromodal pair types were run in complete 5 × 5 factorial designs. Owing to an error, the design for the homomodal pairs was triangular, not a complete factorial, but that did not affect the results.

A small and a large stimulus end anchor, constructed from corresponding single stimuli, were used for each type of pair. The small and large lengths were 2 and 25 cm., the small and large circles were 1 and 8 cm., and the small and large weights were 100 and 800 gm. These end anchors had their usual purposes, including that of reducing end effects in the rating scale (e.g., Anderson, in press-a, in press-b; Eriksen & Hake, 1955, 1957).

Procedure

The *S* was instructed to judge the "total intensity" of each pair of stimuli. Ten practice trials covering the stimulus range were given for each type of pair. The first 2 were the small and large anchors, presented with instructions that they should be called 1 and 20, respectively, with the other pairs to be given intermediate numbers according to their total magnitude.

Pairs involving length and area were presented by placing the 2 stimuli in front of *S*. Pairs involving weight were presented by having *S* lift the weight while looking at the other stimulus.

One replication of the 5 stimulus designs was run in each of 3 sessions. Practice was given only in the initial session, but the 2 anchors were presented anew before each later replication. In each replication, the length–area pairs were presented first, followed in order by length–weight, area–weight, length–length, and area–area. Responses for each stimulus pair were recorded on an index card. The deck of cards for each stimulus type was shuffled for each replication for each *S* to balance order effects. The *S*s were 20 students or similar members of the university community who were paid $5.64 for the 3 sessions.

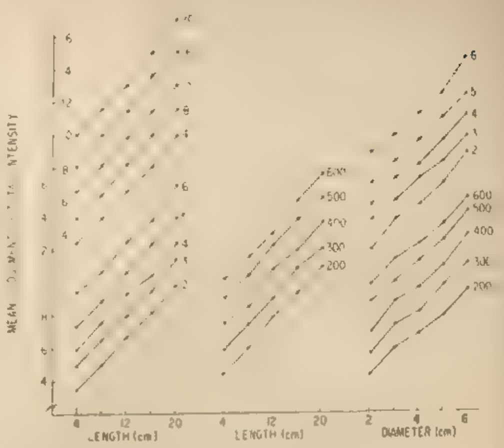

FIGURE 1. Parallelism test of integration model. (Vertical axis represents mean judgment of total magnitude. Lower panels for heteromodal stimulus pairs; upper panels for homomodal stimulus pairs.)

Results

Integration Model

The mean judgments of the stimulus pairs are presented in Figure 1. Each lower panel shows one heteromodal type, plotted in the format of the 5 × 5 design. The values of one design factor are given on the horizontal, and the values of the other design factor are listed by each curve. The 2 upper panels show the homomodal data plotted analogously. For comparison, the upper panels are plotted as though a complete factorial rather than a triangular design had been used; each point connected by a dotted line is identical with a corresponding lateral point connected by a solid line.

The key property of these data is parallelism. The simple adding model predicts that each set of curves should be parallel, and that is essentially true. A rigorous test of parallelism is available

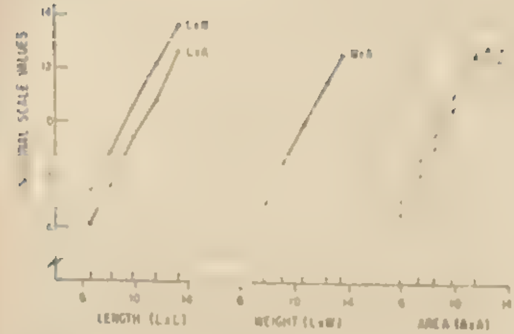

FIGURE 2. Linearity test of cross-task consistency. (Each curve represents the functional scale from one type of stimulus pair plotted against the functional scale from another type of stimulus pair.)

from analysis of variance; the ordinary Row × Column interaction tests for significant discrepancies from parallelism. This interaction did not approach significance in any test, F (16, 304) = 1.49, .79, and .78, in the 3 respective panels. The 3-way interactions with replications were also nonsignificant. Similar tests are possible for the 2 triangular designs (Anderson, 1972b), but were not made in view of the evident parallelism in the graphs.

The simplicity of this analysis is notable. Simply plotting the raw ratings gives an immediate graphical test of the integration model. The parallelism property jointly validates the integration model and the response scale since in general both must hold for parallelism to obtain. Functional scales of the subjective stimulus values are also available. These are considered next.

Functional Scales

Since the model has passed the parallelism test, subjective scales of the stimuli can readily be obtained. According to functional measurement theory, these are just the marginal means of the factorial design.

Scaling can be illustrated for the Length × Area data in the lower left panel of Figure 1. The vertical spacing of the curves constitutes an interval scale of the subjective values of the areas. The curves for circles of 2- and 3-cm. diameter appear to be closer together than the curves for circles of 5- and 6-cm. diamete[illegible] Thus, subjective circle value appears t[illegible] ow a small positive acceleration as a [illegible]ction of physical diameter. In this sa[illegible] plot, the mean curve yields a scale of f[illegible]ional length. It is almost linear in [illegible]s of physical length.

Functional scales from the oth[illegible] fac-torial designs are obtained in [illegible] same way. Scale values from the t[illegible]ular designs can be obtained analogou[illegible]

Cross-Task Validation

Three functional scales of sub[illegible]tive length are available since the length [illegible]timuli were used in 3 types of pairs. [illegible] the same subjective values function in each of the 3 integration tasks, each l[illegible]ngth scale should be a linear function of each other length scale.

This test of cross-task consisten[illegible] is shown in Figure 2. In the left pan[illegible], the functional scale of length from the L[illegible]ngth × Length design is plotted on the hori-zontal axis. The other 2 functional scales of length, from the Length × Area and Length × Weight designs, are plotted on the vertical. Both curves are essentially linear. Thus, the subjective values of length are indeed the same, up to a linear transformation, across all 3 integration tasks.

The center panel plots subjective weight from the Area × Weight design against subjective weight from the Length × Weight design. The right panel shows subjective area from the Length × Area and Area × Weight designs as a function of subjective area from the Area × Area design. All these curves appear linear. In general, therefore, the same subjective values appear to function in each task.

Psychophysical Law

Once the subjective stimulus values have been obtained, the psychophysical law can be obtained very simply. It corresponds to the graph of these subjective values as a function of the objective physical values. These graphs are shown in Figure 3.

The 3 psychophysical functions for length (left panel of Figure 3) are all

essentially linear. This result agrees with most previous work on length.

The center panel plots the 2 psychophysical functions for heaviness. Both show a slight downward convexity. This shape, which would correspond to an exponent slightly less than 1 in a power function, agrees with previous work in this program (Anderson, 1970a, 1972a). In contrast, magnitude estimation yields an exponent around 1.45 (Stevens & Galanter, 1957). This disagreement is considered further in the Discussion section.

The 3 curves in the right panel of Figure 3 show the psychophysical function for area. These appear to have some upward convexity, as might be expected since physical area would itself be convex upwards as a function of circle diameter.

It should be noted, however, that a linear function would give a reasonable fit to these curves for area, suggesting a tendency to rely on the diameter, perimeter, or other linear aspect as a measure of the magnitude of the circle. Since such a tendency might be potentiated by the present array of tasks, these scales for area may be task specific. More appropriate scales of area might be obtained by restricting to designs with areas only and by emphasizing area judgments in the instructions. Thus, circles could be paired with triangles, crosses, or disks. This procedure could also provide subjective scales for irregular figures by applying a 2-stage model (Anderson, in press-a; Anderson & Weiss, 1971).

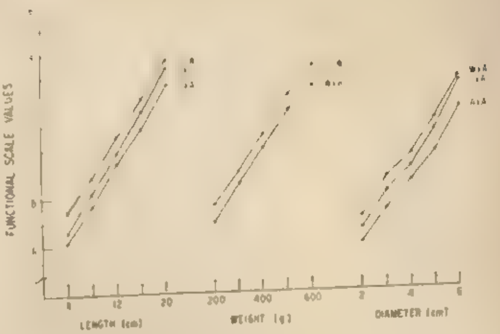

FIGURE 3. Psychophysical functions: Functional stimulus scales are plotted against the physical values.

Related Work on Weight Adding

Curtis and Fox (1969) applied an adding model to judgments of sums of 2 lifted weights. They reported a good fit for their rating data, in agreement with tests of an averaging model for lifted weights (Anderson, 1967; Anderson & Jacobson, 1968).

However, these 2 integration tasks, summing and averaging, have produced a seeming disagreement about the psychophysical function for lifted weight. The relevant reports all agree that the psychophysical function is convex downwards, which would correspond to an exponent less than 1 in a power function. However, Curtis and Fox (1969) reported an exponent around .65, whereas Anderson (1972a) claimed a near linear function by visual inspection. This seeming disagreement prompted further analysis of the previous data, and 3 main points need mention.

Data analysis. First, S. J. Rule (personal communication, March 16, 1973) fit a power function to Anderson's (1972a, Figure 3) data, obtaining an exponent of .69. This value is close to that of Curtis and Fox (1969). With a fixed response range, of course, the difference in stimulus ranges (10–218 gm. in Curtis and Fox, 200–600 gm. in Anderson) would itself produce some difference in the exponent of a power function fit (Poulton, 1968). It may be worth adding that a logarithmic function remains invariant, changing only in its base to adapt different stimulus ranges to a fixed response range.

Second, the present author reanalyzed the category rating data of Curtis and Fox (1969) using functional measurement to test the adding model. Analysis of variance for triangular designs (Anderson, 1972b) was applied separately to each single subject and to the group as a whole. These analyses supported the adding model fairly well. For the group data, deviations from additivity were not significant tested against the *S*s × Pairs interaction, F (20, 243) = .97. Of the 10 single *S*s, 2 or 3 did show significant discrepancies, tested against individual within-cell variability, but these did not seem to be overly serious.

For category ratings, therefore, the data of Curtis and Fox (1969) agree well with results on stimulus integration obtained by the author in the present and previous reports.

Third, the present author also reanalyzed the magnitude estimation data obtained by Curtis and Fox (1969). In the individual analyses, 7 of the 11 *Ss* showed marked discrepancies from the adding model, with 6 of the 7 *F* ratios significant beyond the .001 level. If the adding model used by Curtis and Fox is correct, magnitude estimation cannot be valid.

In the group magnitude estimation data, these individual discrepancies from the adding model averaged out. Indeed, the adding model fit the group means quite well, F (19, 260) = .34, for deviations from additivity. The group geometric means were not much different from the arithmetic means, in part perhaps because of the choice of standard and modulus in this particular experiment. This example illustrates the risk in the standard procedure of averaging magnitude estimation data across *Ss*.

Statistical analysis. The statistical analysis used by Curtis and Fox (1969) has certain limitations that need to be pointed out. The basic limitation is that it does not provide an adequate test of the adding model. In slightly changed notation, their 2-stage model would read

$$R = a(S_1^k + S_2^k)^m + b,$$

where S_1 and S_2 are the physical values of the 2 stimuli, R is the observed response, k and m are power function exponents, and a and b are constants.

They fitted this equation using the standard, nonlinear least squares analysis to estimate the exponent parameters in the above equation. Such analyses also purport to give certain statistical reliability information, including standard errors of the parameters, together with an overall F test of deviations from the model. This reliability information, unfortunately, has little value because it rests on the assumption that the fitted model is correct. In this analysis, deviations from additivity, from the power functions, or both, go into the error term. Incorrectness in the model thus tends to obscure itself because it inflates the error term. To the best of the present author's understanding, this kind of analysis needs to be restricted to the single *S*, and requires an error term based on within-cell variability for each *S*.

The functional measurement procedure may be useful in further study of the 2-stage model. It is more general than the procedure used by Curtis and Fox (1969) because it requires no assumption about the psychophysical stimulus function. Indeed, no physical metric is needed for the stimuli which may have merely nominal values. General response transformation is also allowable (Anderson, in press-a, Section II, A, 6; Bogartz & Wackwitz, 1971; Weiss, 1973). Thus, a rigorous test of the basic model is feasible while allowing for general input and output functions.

It should be emphasized that the present analyses have reached the same conclusions as Curtis and Fox (1969), excepting only the present finding of substantial discrepancies in the individual data on magnitude estimation. The limitations in their statistical technique are not of present importance, therefore, but they need mention because similar techniques have been employed in related reports. These statistical tests of goodness of fit are important because the theoretical interpretation depends on whether or not the basic algebraic model is correct.

Other Related Work

The heteromodal integration task was introduced by Feldman and Baird (1971) who tested an adding model (arithmetic mean) and a multiplying model (geometric mean) for judgments of total magnitude of stimulus pairs that consisted of a sound and a light. Their graphs suggest that the adding model did better, but they do not provide a test of goodness of fit. The functional measurement procedure would give a much simpler and more powerful analysis. The adding model predicts parallelism, while the multiplying model pre-

dicts a bilinear form (Anderson, in press-a, Section II, B, 6; in press-b, Section 7.12).

Dawson (1971) studied sum and difference judgments of circular area and of loudness, and Marks and Cain (1972) studied difference judgments of circular area, heaviness, and roughness. Both reports concluded that there were systematic discrepancies from the sum and difference models. However, these discrepancies may merely result from bias in the magnitude estimation response.

One other report on sum judgments should also be noted. Five experiments on length adding in a thoughtful article by Kreuger (1970) all found systematic overestimation of the combined length of 2 or 4 lines, relative to judgments of single line controls. Although Kreuger concluded that the integration procedure itself introduced a bias into the length production response, a simple adding model may be able to account for his data. To a large extent, though perhaps not completely, the overestimation could reflect a constant error introduced by the combining process. That would be consistent with the rough tendency toward constant overestimation across different lengths, and with the greater overestimation for 4 lines than for 2 lines.

Discussion

Integration Theory

The present data support the adding model for psychophysical integration in all 5 cases. The simple parallelism test of Figure 1 accomplishes 3 goals simultaneously (Anderson, 1970a, Figure 1): (*a*) It validates the integration model (psychological law), (*b*) it validates the response scale, and (*c*) it yields interval scales of subjective stimulus value.

Numerical response measures, such as ratings, may well fail to be interval scales. But if the ratings were not an interval scale, a correct model would fail the parallelism test. That test, therefore, provides a joint validation of the model and of the response scale. The stimulus scales derive from the model as already shown.

The basic element in this functional logic is the integration model. It is the structural frame on which response and stimuli are scaled. The simple adding task may seem trivial in itself, but it has an important theoretical role to play (Weiss & Anderson, 1969, 1972).

Magnitude Estimation Seems to be Invalid

The present results imply that magnitude estimation is biased and invalid. It has been repeatedly emphasized (e.g., Stevens, 1957, 1966, 1971) that ordinary ratings and magnitude estimations are nonlinearly related for prothetic dimensions such as were used here. This point is well illustrated by the present psychophysical function for lifted weight which would have an exponent less than 1 in a power function fit. In contrast, magnitude estimation yields exponents around 1.45 (Stevens & Galanter, 1957; see also Stevens & Rubin, 1970). Being nonlinearly related, ratings and magnitude estimates cannot both be interval scales of the same thing. At least one is invalid.

The present rating data have satisfied 2 validity criteria. The parallelism test of Figure 1 demonstrates within-task consistency, providing one basis for concluding that the rating response is an interval scale. The linearity test of Figure 2 demonstrates cross-task consistency, thus giving generality to the concept of stimulus scale value. Since these results support the validity of the rating response, they imply that magnitude estimation is invalid.

This experiment does not stand alone. Three other lines of evidence support the same conclusion. The first is a program of work in the author's laboratory that has provided substantial support for simple algebraic models of psychophysical integration. In particular, Anderson (1972a) showed within-task and cross-task consistency of heaviness scales obtained from weight averaging and from the size-weight illusion. Also, Weiss (1972) made a direct comparison in grayness averaging and found that ratings satisfied the parallelism prediction and magnitude estimation did not.

The second line of evidence comes from other work on psychophysical integration. Studies by Curtis and his colleagues have generally found that magnitude estimations do not fit sum and difference models, unless perhaps they are nonlinearly transformed. These same studies have also generally appeared favorable to ratings though correct tests of fit have been lacking as noted above. Fundamental work by Birnbaum and Veit

(in press) can also be most simply interpreted to support ratings as opposed to magnitude estimations.

The third and final line of evidence comes, curiously enough, from social psychology. Using social stimuli, Stevens (1966) has found the same nonlinear relation between ratings and magnitude estimations that is obtained with prothetic psychophysical dimensions. He concluded that ratings show the same general bias in both cases. However, a long-extended program of work by Anderson (1962, in press-b) has found that ratings also satisfy a class of algebraic integration models in the social field. Basic work in decision making by Shanteau (e.g., 1970, 1972) has also supported the functional measurement approach.

The social data have particular interest. Unlike most psychophysical dimensions, many social dimensions have both positive and negative values. Such data make it plausible to rule out geometric averaging models and analogous models that might seem compatible with magnitude estimation data (Anderson, 1972a; Birnbaum & Veit, in press; Weiss, 1972).

Integration and Valuation

Heteromodal integration raises an interesting question about process. Since length and weight are qualitatively different sensations, how can they be added together? To handle this conceptually, it would seem reasonable, if indeed not necessary, to suppose that the different stimuli are changed into some common currency for the demands of the immediate task. Sensations are not themselves added, but rather their processed values.

Integration theory handles this matter in terms of a valuation operation. Any task defines a judgment dimension, implicitly or explicitly. The valuation operation produces the scale value of the stimulus, and its weight, in relation to this judgment dimension.

But this view requires that the scale value depend on the integration task because that controls the valuation operation. It would be premature, therefore, to claim that scale values from any one task will measure the magnitude of a basic sensation. Each task imposes its own valuation operation, and these may be nonlinearly related across tasks. That is certainly true for verbal stimuli. Even for a simple tone, scale value will depend on whether *S* is set to judge loudness or pitch.

In this view, the subjective magnitudes that are studied in psychophysical judgment may be rather distant derivatives from any basic "sensation." The commonsense view, that there is a direct relation, may well be correct, but it requires justification. Confidence in any measure of sensation would thus seem to rest on a concept of cross-task scale invariance.

Need for such cross-task validation agrees with the emphasis on converging operations by Garner, Hake, and Eriksen (1956), and in an important article by Birnbaum and Veit (in press). Similarly, Weiss and Anderson (1969) commented on scale invariance in psychophysics that "The validity of functional measurement will depend on getting the same scales with different integration tasks [p. 63]." The present and previous reports (Anderson, 1972a) have demonstrated such cross-task scale invariance.

The Psychological Law

The disagreement between magnitude estimation and rating methods is only a surface reflection of a deeper difference. Indeed, since functional measurement explicitly allows for monotone transformation, it could make direct use of magnitude estimation data by transforming out the bias.

The deeper difference appears in the validity criterion. Functional measurement rests on the use of some algebraic model; that provides the scaling frame and the validity criterion. But in the magnitude estimation approach, these integration models have been largely disavowed (Stevens, 1971; see also Anderson, in press-a, Section IV, B, 4).

This difference in methodology comes from a shift in conceptual orientation, away from the psychophysical law and toward the psychological law. The prime concern and emphasis in work with magnitude estimation has been with the psychophysical law, that is, with the relation between subjective magnitude and the physical values of the stimulus. The functional measurement approach is primarily concerned with the psychological law, in particular, with models of stimulus integration. Accordingly, the basic problems are substantive problems of stimulus integration. Measurement in general, and the psychophysical law in particular, are derivative from the psychological law. In this respect (Anderson, 1970b, in press-a), functional measurement is a reaffirmation of the spirit of a long tradition in psychophysical judgment.

STIMULUS FAMILIARIZATION AND CHANGES IN DISTRIBUTION OF STIMULUS ENCODINGS[1]

ALLEN R. DOBBS[2]

University of Alberta, Edmonton, Alberta, Canada

Independent groups were given 1 or 10 familiarization trials on integrated (consonant vowel consonant word) or nonintegrated (consonant consonant–consonant) trigrams. The 4 groups ($n = 48$) were then given a stimulus recognition task containing the following 4 types of items: (*a*) the original stimuli, and distractor items having their (*b*) first, (*c*) second, or (*d*) third letters in common with the original stimuli. The probability function for encodings isomorphic with letters from the 3 letter positions was inferred from false identifications. Sixteen *S*s from each group then learned 1 of 3 types of paired-associate (PA) list wherein the stimuli were the familiarized items. Encoding during PA learning was inferred from a stimulated-recall task given after PA learning. Contrary to the 1968 conclusions of Martin, the results indicated that stimulus-only familiarization resulted in selective encoding of nonintegrated stimuli. Although those changes did not affect the *rate* of PA acquisition, familiarization did affect stimulus encoding during PA learning.

The stimulus encoding variability hypothesis advanced by Martin (1968) proposes that the perceptual encoding response to a verbal unit may vary on successive exposures, and that the amount of this variability is negatively correlated with the degree to which the unit is integrated. Highly integrated units such as consonant–vowel–consonant (CVC) words are assumed to be consistently encoded on successive paired-associate (PA) trials, and it is this encoding stability which is postulated to underlie the relatively rapid acquisition of lists having integrated-stimulus items. Lists which contain unintegrated (low meaningfulness, *m*) stimulus units, such as low *m* CCCs, are acquired more slowly, and it is postulated that this decreased learning rate is due to the lack of initial stable encodings for unintegrated units. However, stability of encodings for unintegrated stimuli is assumed to vary across trials. Specifically, it is assumed that there are initial probabilities for the elicitation of the various possible encodings of unintegrated stimuli, that this probability density function (PDF) shifts toward degeneracy for a single encoding early in learning, and then becomes more platykurtic with overlearning. That is, the initial PDF distribution is assumed to shift such that a single selective encoding becomes dominant early in learning, but all encodings become equally probable during overlearning training. Although it is left unspecified as to why or by what mechanism the PDF shifts to degeneracy, it seems clear that Martin considers the cued-recall situation to be a necessary condition. This appears intuitively reasonable, as the functional value of stable selective stimulus encoding during PA learning is obvious, whereas it is difficult to see why individuals would selectively encode at all in a stimulus-only familiarization task. There are also data available which are, at least, not incompatible with this notion. For example, Schulz and Martin (1964) have reported that stimulus familiarization, consisting of aural (spelled) presentation and requiring recall, was found not to have a differential effect on the subsequent rate of PA learning for several levels of stimulus *m*.

On the basis of these data and the Martin (1966) results, Martin (1968) has concluded that increases in stimulus recallability, such as that produced by stimulus-only familiarization, does not affect the acquisition of an

[1] This research was supported by Grant APA 335 from the National Research Council of Canada. Dona Carlson and Marvi Blackmore assisted in conducting the experiment. Bryce Schurr and Susan Schurr assisted in the analyses.

association between an encoding(s) and the response term differentially over levels of *m* (or integration). Further, he stated that this

> therefore implies that independent familiarization with a nominal stimulus does not alter the distribution of probability density over $\{r_1 - s_1\}$ [the encodings], at least not in a way that changes the availability of one alternative encoding relative to another for purposes of incorporation into an overt-response-producing association [p. 423].

It is not at all clear that this conclusion is necessitated by the data from the Schulz and Martin (1964) study, for it is possible that the PDF for encodings is altered by stimulus-only familiarization, and this change may carry over to encoding during PA learning in such a way as to systematically alter the availability of possible encodings for incorporation into overt-response-producing associations, *but still not* differentially change the rate of association formation. This interpretation is also consistent with the Schulz and Martin data.

In order to differentiate between these 2 possible interpretations, a more direct test is needed of the effects of stimulus-only familiarization on the PDF for various encodings, and of the type of encoding used during PA learning as a function of the amount of stimulus-only familiarization. Support for Martin's (1968) interpretation would be obtained if the data indicated no change in the PDF for various encodings with increased stimulus-only familiarization, and if there was no difference in stimulus encoding during PA learning as a function of the amount of stimulus-only familiarization.

The present experiment was designed to provide this information. First, independent groups were familiarized for 1 or 10 trials on materials differing widely in the degree to which they are integrated. High *m* CVC words were selected to represent the highly integrated units, and low *m* CCCs were employed as the unintegrated units. The PDF for encodings isomorphic with letters from Positions 1, 2, or 3 of the trigram stimuli was then inferred from the false identifications made during a stimulus recognition task given immediately after familiarization. The effect of stimulus familiarization on the rate of PA learning was then assessed for 3 types of lists. It was assumed that if any shift in the PDF occurred, it would be toward greater selective encoding of the initial position, at least for the unintegrated stimuli. On the basis of this assumption, 3 types of PA lists were constructed and administered to independent groups: For one type of list, selective encoding of the first-position letter would facilitate list acquisition, for another it would lead to interference, and for the third there should be no effect. These conditions were manipulated by varying the relationship of the initial letters of the stimulus and response terms. Finally, a stimulated-recall test was administered in order to assess whether the type of encoding employed during PA learning was a function of stimulus-only familiarization.

Nonrecall familiarization was employed in the present study because it does not impose task demands with regard to stimulus terms which may be in opposition to those of the PA task. That is, familiarization requiring recall would seem to demand that individuals not stimulus (letter) select, whereas in a PA task they tend to do so with nonintegrated stimulus materials (Postman & Greenbloom, 1967). The nonrecall procedure would appear to introduce no biases since the essence of Martin's (1968) conclusions concerning familiarization have to do with stimulus repetition outside the context of a cued-recall situation, and stimulus availability in the sense of recallability is undoubtedly also correlated with the amount of nonrecall familiarization.

Method

Design and subjects. The overall experiment consisted of a $2 \times 2 \times 3$ factorial design. The respective sources of classification were unit integration (high vs. low), number of familiarization trials (1 or 10), and appropriateness of familiarization encoding (same, same re-paired, and different). The appropriateness conditions were formulated primarily for the low-integration (low *m* CCC) stimuli on the basis of 2 assumptions. First, it was assumed that *S*s do selectively encode low *m* CCCs during nonrecall stimulus familiarization, and second, that this encoding would be in accordance with information

theory analyses (Aborn & Rubenstein, 1958; Carson, 1961; Garner, 1962). That is, that there would be a shift in the encoding PDF away from the middle letter, with the predominance of the shift being directed to a selective encoding of the initial letter. On this basis, selective encoding (first letter) was "appropriate" for the same (S) condition, in that paired stimulus and response terms had identical first letters. It was inappropriate for the same re-paired (S_r) condition as the items from the S list were re-paired. In the different (D) condition, all stimuli and responses began with different letters and provided a baseline for evaluating the effects of the S and S_r list constructions.

The *Ss* were 144 University of Alberta undergraduates whose experimental participation was in partial fulfillment of an option for a course requirement, and 48 paid volunteers from an introductory psychology summer course. These latter *Ss* were equally divided among all conditions. Since no differences were detected between the 2 "sets" of *Ss*, they were grouped together in all analyses presented herein. Eight males and 8 females were assigned randomly to each of the 12 groups, with the restriction that each group must have $n - 1$ *Ss* prior to the assignment of the *n*th *S* to any group.

Procedure and materials. The experiment was conducted in 4 phases. Phase 1 consisted of 1 or 10 stimulus familiarization trials on the integrated (CVC) or unintegrated (CCC) materials. A trial consisted of a 2-sec. presentation of each of the 5 stimulus terms. The *Ss* were instructed to read silently each set of 3 letters, as it appeared, but were not asked to memorize the list. During Phase 2, the 4 Phase 1 groups received a stimulus recognition task. The recognition list consisted of 4 kinds of items: (*a*) original, and distractors which had (*b*) first, (*c*) second, or (*d*) third letters in common with the original items. The original items each appeared 3 times, and there were 2 examples of each of the 3 kinds of distractors per original item. These 45 items were presented individually with *S* self-pacing, and ordered randomly with the restriction that the same *type* of item could not occur on 2 successive presentations. The *Ss* were informed of the repetition of original items and instructed to identify the original item by saying *same*, but to respond with *different* when they thought the presented item was not *identical* to an item from Phase 1. *Same* responses to distractor items were taken as evidence for selective encoding on the position of the letter common to an original item.

Each of the 4 groups was divided to form the S, S_r, and D conditions of Phase 3 PA learning. The study–test method was employed with a 2:2-sec. rate of presentation with a 2-sec. intertrial interval.

The Phase 4 stimulated-recall task was identical to the recognition task employed in Phase 2 except that after making each *same-different* discrimination *S* was also instructed to give the first response from the PA list that the item made him think of.

One of the objectives of the present study was to evaluate the stimulus encodings employed during PA learning by means of the Phase 4 stimulated-recall task, and to compare these with [illegible] encoding changes assessed in Phase 2 which might be obtained as a result of differential stimul[illegible]arization. Since the form of encoding PD[illegible] [illegible]ssumed by Martin (1968) to be, in part, a functi[illegible] degree of learning, and since list criteria re[illegible] often widely varying levels of individual-it[illegible] [illegible], an apparatus was constructed to cont[illegible] the variable as carefully as possible. Th[illegible] stimulus materials were presented on IEE Series [illegible] digit display units programmed by means of [illegible]-tape reader. A series of switches allowed fo[illegible] immediate removal and replacement of any [illegible] of the items at any time. When an *S* correctly r[illegible] an item on 2 successive trials, the item wa[illegible] removed from the list and replaced by a pair [illegible] considerably different classes of materials [illegible] interference. The replacement items were [illegible] form–2-digit number pairs. Phase 3 in[illegible] noted the possibility of changing items [illegible] emphasized attending to both types of pairs. [illegible] data indicated that the instructions were successful [illegible] that *Ss* did learn the replacement items, and were able to successfully recall them at the con[illegible] of the experimental session.

Materials. The unintegrated stimulus [illegible] consisted of CCC trigrams having a mean Witmer (1935) *A* value of .33. The integrated sti[illegible] were all 1.00-*a*-value CVC words (Noble, 1961). [illegible] Thorndike and Lorge AA nouns served as respons[illegible]. The distractor stimuli had a mean Witmer *A* [illegible] of .38 and a Noble *a* value of .98 for the low and high stimulus sets, respectively. Since, excluding Y, there are only 5 vowels, the vowels were repeated in the CVC distractors. For comparability, the middle letters of the original-stimulus CCC terms were treated in the same manner. Although this necessitated a confounding in the sense that all types of distractor items had their second letters in common with an original item, no distractor item was allowed to have 2 letters in common with an original item. Further, this confounding should have no differential effect on the assessment of first and third position encoding, nor should any effect be differential for second position between groups, at least within integration levels. The 5 CCCs take 15 consonants leaving only 4 consonants. Only these 4 consonants served as different letters in the distractors. To equate for this, only 4 different consonants were used in the CVC distractors.

RESULTS

Stimulus recognition (Phase 2). The primary objective of Phase 2 was to assess familiarization-induced changes in the PDF for encodings isomorphic with letters from Positions 1, 2, and 3 of the trigram stimuli. The false recognition data shown in Figure 1 are plotted in terms of means of proportions of total recognition errors per *S* on distractor stimuli attributable to identities

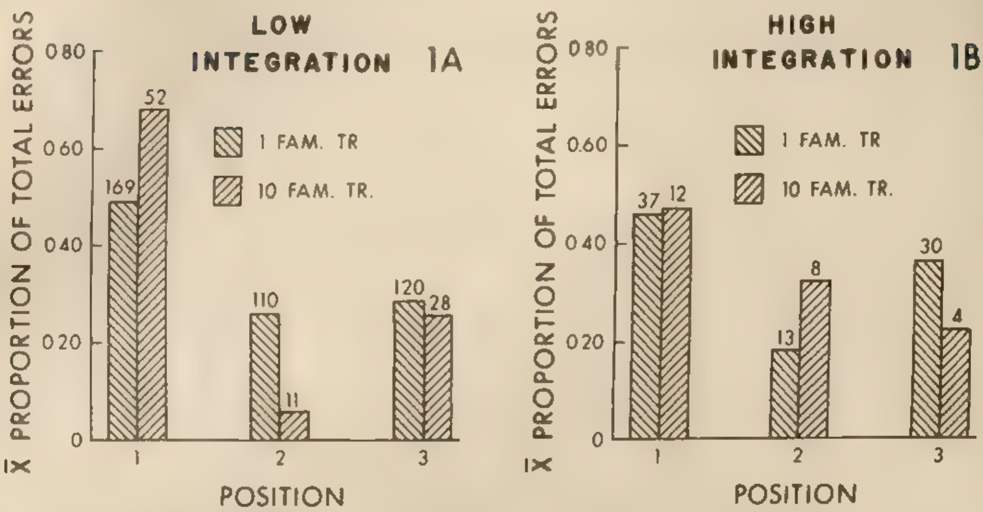

FIGURE 1. Mean proportion of the total number of false recognition errors in Phase 2 attributable to distractors having letters in Positions 1, 2, or 3 identical to original stimuli for low-integration (Figure 1A) and high-integration (Figure 1B) materials. (The numbers represent the frequencies of each type of error.)

in each of the 3 positions. The numbers above the bar graphs in both figures indicate the total number of errors given to each type of distractor item for each of the conditions.

The total number of errors (false identifications) were analyzed using a 2 × 2 × 3 analysis of variance with the factors being integration level (high or low), 1 or 10 familiarization trials, and a within-*S*s variable of first-, second-, or third-letter identity position. The trend shown by the *numbers* in Figure 1 for a greater overall level of number of errors to be made with low-integration stimuli was reliable, F (1, 188) = 86.05, $p < .01$, as was the trend for there to be fewer errors after 10 familiarization trials, F (1, 188) = 76.52, $p < .01$. The interaction of these 2 variables was also reliable, F (1, 188) = 36.68, $p < .01$. The interpretation of the *overall* false identification rates are somewhat ambiguous, as it is unclear whether an individual false identification represents a genuine recognition failure or merely a change in bias for emitting *same* responses as a function of the familiarization conditions. However, any such change in bias cannot differentially affect the within-*S*s *distribution* of errors across the 3 positions, and these are the data of primary concern in evaluating the PDF for the various letter encodings. Similarily, interactions involving the within-*S*s position variable are also unaffected by such a potential change in bias.

The trend for *S*s to differentially distribute their false recognitions across distractor items indicating different types of selective encodings was statistically reliable, F (2, 376) = 26.82, $p < .01$. Most importantly, the distribution of errors depended upon the level of familiarization, as indicated by a significant Familiarization Trials × Position interaction, F (1, 188) = 36.67, $p < .01$. Contrary to Martin's (1968) conclusion, this interaction indicates that there is a change in the PDF for encodings as a function of stimulus-only familiarization. However, the analysis also indicated a statistically reliable Position × Integration Level interaction, F (2, 376) = 9.12, $p < .01$, and because of this interaction the data for high- and low-integration stimuli were further analyzed separately. Further, since the primary interest in evaluating the false identifications was not in the number of errors per se, but rather in terms of, given that an error was made, what kind of encoding did it represent, the remaining analyses are in terms of

the proportions of total errors per S which could be attributed to the 3 position encodings.

As can be seen from the Figure 1A, the proportions of false recognitions for the unintegrated stimuli for Ss given 1 familiarization trial are nearly rectilinearily distributed over the 3 positions. However, 10 familiarization trials resulted in a shift in the distribution of recognition errors away from Position 2 towards Position 1, indicating a trend for selective encoding of the initial letters with increased familiarization. The data from those Ss who made at least one error were analyzed in terms of a 2 × 3 analysis of variance, where number of familiarization trials and a within-Ss position variable were the factors. In this analysis, the overall proportion of errors summed across position for each S is of necessity 1.00. Consequently, no consideration could be made of the between-Ss aspects of the analysis. On the other hand, the position factor and the Position × Number of Familiarization Trials interaction were of direct concern. Since these are both within-Ss comparisons, the lack of between-Ss variance can have no effect on this portion of the analysis. The analysis confirmed the trend for the proportions of errors to be differentially distributed across the 3 positions, F (2, 144) = 47.61, $p < .01$. Further, the reliable interaction, F (2, 144) = 12.97, $p < .01$, indicated a shift in the encoding of unintegrated stimuli with familiarization training. Internal analyses showed that the differences between 1 and 10 familiarization trials for both Positions 1 and 2 were reliable, ts (144) = 3.66 and 3.17, respectively, ps < .01.

Contrarily, proportions of recognition errors for integrated stimuli indicate an initial encoding distribution which is in accordance with previous investigations of positional information of words (e.g., Horowitz, Chilian, & Dunnigan, 1969; Horowitz, White, & Atwood, 1968). That is, the majority of errors were obtained with first- and last-position identity, with identity in the middle position resulting in but few errors. Interestingly, a shift of the error distribution to first, seco[nd, and] third, in order of decreasing percentages [of e]rrors, resulted when 10 familiarization t[rials] were given. This indicates a possible t[ren]d for a shift to serial processing of CV[C] word materials after several familiarizati[on t]rials. However, an analysis identical to [the] one performed on the low-integration d[ata] did not indicate a reliable interaction. Consequently, it must be concluded at [pre]sent that familiarization training does n[ot a]ffect the PDF for the positions of high m [CV]Cs.

It may also be of some interest to ex[a]mine the number of original-item correct [re]cognitions. For the high-integration st[im]uli, the means were 12.77 and 14.46 fo[r] the groups given 1 and 10 familiarization t[ri]als, respectively. These means for the low–1- and low–10-trial groups were 10.15 and 13.52. For all groups SDs ranged [1].47–2.37. The trend for high-integration stimuli to be better recognized was reliable, F (1, 188) = 38.78, $p < .01$. In addition, the trend for the 10-trial task to facilitate recognition of low-integrated stimuli to a greater extent was also statistically reliable, F (1, 188) = 8.70, $p < .01$. However, this interaction was probably the result of a ceiling effect for the high group receiving 10 familiarization trials (38 of 48 Ss showed perfect recognition). An analysis of the total number of *same* responses emitted regardless of whether they were correctly given indicates that it is doubtful that these findings can be attributed to differential bias levels for the 4 groups. A total of 678, 718, 876, and 740 *same* responses were given by the high–1, high–10, low–1, and low–10 groups, respectively. These totals show a trend for the overall number of *same* responses to increase with greater familiarization for the high groups and to decrease with familiarization for the low groups. The interaction was statistically reliable, F (1, 188) = 13.64, $p < .01$. Since the overall trends for the tendency (bias?) to emit *same* responses are opposite to the trends for the *same* responses which indicated correct recognitions, it does not appear that the findings regarding the correct recognition data need be qualified.

In summary, the present data indicate

that nonrecall familiarization trials have several effects: (*a*) False recognitions indicate that after only one familiarization trial the dominance of letter encodings are in the order of first, last, second for integrated (CVC word) items, whereas there is a nearly rectilinear distribution of codings for unintegrated (CCC) stimuli. (*b*) Higher levels of familiarization result in a shift of the probability distribution of letter encodings for unintegrated items to first, last, second in order of decreasing dominance, but have little effect on the probability distribution of letter codings for integrated items. (*c*) Higher levels of familiarization result in more correct identifications of the familiarized items, and this facilitation may be more pronounced regarding unintegrated items.

Paired-associate learning (*Phase 3*). It will be recalled that during PA learning each item was only presented until it was correctly responded to on 2 successive test trials. Consequently, there was a trials-to-criterion score for each item. These item trials-to-criterion scores were averaged for each *S* yielding a mean trials-to-criterion score for each *S*. The data presented in Table 1 and used in all Phase 3 analyses were in terms of group averages of *S* mean trials to reach criterion. These data were analyzed by means of a 2 × 2 × 3 factorial design, where the factors were integration level, familiarization, and appropriateness, respectively. The analysis revealed statistical reliability for the integration level, F (1, 180) = 12.44, $p < .01$, and appropriateness, F (2, 180) = 32.64, $p < .01$, variables, as well as for the Integration Level × Appropriateness interaction, F (2, 180) = 4.86, $p < .01$. None of the remaining tests approached significance (largest $F = 1.004$). Since the dropout procedure was employed, a similar analysis was conducted which excluded the contribution of the last-learned item. This analysis revealed the same pattern of results except that the potential Integration Level × Familiarization × Appropriateness interaction was more exaggerated though not statistically reliable, F (2, 180) = 2.09. Although there is a trend for both the

TABLE 1

Phase 3 Paired-Associate Performance (Group Averages of *S* Mean Trials to Criterion) as a Function of the Relationship between the Stimulus and Response Term First Letters, Amount of Prior Stimulus Familiarization, and Stimulus Integration

Paired-associate list	Low integration		High integration	
	Amount of familiarization		Amount of familiarization	
	1	10	1	10
Same	2.44	2.65	[illegible]	[illegible]
Same re-paired	5.76	5.29	[illegible]	[illegible]
Different	4.70	4.95	[illegible]	[illegible]

high- and low-integration-S, conditions to be affected by familiarization, neither of these trends was statistically reliable in either analyses including all 5 items or ones excluding the last-learned item. Consequently, it was concluded that the integration level and appropriateness conditions affected learning, but that familiarization had no effect on the rate of PA learning. These findings are in accordance with the results reported by Schulz and Martin (1964) and Martin (1966). Consequently, the data from Phases 2 and 3 taken together indicate that stimulus-only familiarization of unintegrated units does affect the PDF for letter encodings, and that this change in encoding dominance does not necessarily lead to an alteration in the *rate* of PA list acquisition.

Stimulated recall (*Phase 4*). The primary objective in analyzing the stimulated-recall data was to assess false recognitions of the distractor stimuli which were followed by a PA-list response associated with the critical letter of the distractor during Phase 3 learning. Within the context of Martin's (1968) stimulus encoding variability hypothesis, the critical data are any evidence of differences in the distribution of such responses across the various types of distractors as a function of familiarization. Should such differences be realized, they would imply that stimulus-only familiarization does result in a change in the PDF for the encodings (as the Phase 2

TABLE 2

Mean Number of False Identifications in Phase 4 by the Low-Integration Groups which Were Followed by Responses Previously Associated with an Original Item Having a Letter in Common with the Distractor

Critical letter position	1 familiarization trial			10 familiarization trials		
	Same	Same repaired	Different	Same	Same repaired	Different
1	6.44	1.19	1.62	1.69	.56	.75
2	.06	.19	.19	.12	.06	.06
3	.19	.56	.25	.06	.25	.38

data indicated), and familiarization does in fact do so in a way which alters the availability of alternative encodings for purposes of incorporation into overt-response-producing associations. A finding of this type would indicate an effect of familiarization on PA learning (presumably the stimulus encoding phase) even though the *overall* rate of list acquisition was unaffected.

Those *S*s receiving the familiarized integrated items (CVC words) as stimulus terms during the PA task made very few recognition errors to the distractor stimuli which were followed by a "correct response." Only a total of 20 such errors were made by 92 *S*s, and these were not differentially distributed across conditions. It appears then, that stimulus-only familiarization of the integrated stimuli had little effect on the PDF for the various letter encodings (Phase 2 data), and there was no effect of familiarization on encoding during PA learning. This finding is not surprising as it would be anticipated that high *m* CVC words are well integrated and this integration would be little affected by familiarization training.

Contrarily, those *S*s receiving the unintegrated stimuli (low *m* CCCs) made a total of 234 false identifications which were followed by a PA-list response previously associated with an original stimulus item having a letter in common with the distractor. Further, these responses were differentially distributed with respect to the 3 letter positions and the appropriateness and familiarization conditions. Table 2 shows the means for these comparisons. As is apparent from Table 2, there were very few false identifications followed by correct responses to any distractor items, except those having their first letters in common with an original stimulus. Because of the exceedingly small number of identification errors representing encoding on Positions 2 or 3, only the data from the Position 1 items were analyzed. A 2 × 3 (Familiarization Level × Appropriateness) analysis of variance indicated that prior stimulus-only familiarization affected the number of Position 1 false identifications followed by a correct response which were made after PA learning, F (1, 90) = 41.03, $p < .01$. As can be seen from Table 2, each of the 10-familiarization-trial groups made fewer such errors than did their respective 1-familiarization-trial groups. Since very few Position 2 and 3 items were falsely identified, this finding indicates that the 10-familiarization-trial groups knew more about the stimulus items than did the 1-trial groups, whose knowledge was more restricted to the initial letters. Since all groups had reached similar levels of learning during the PA task, this finding may reflect a more platykurtic PDF for the groups receiving a greater degree of stimulus-only familiarization.

The type of PA list also influenced the number of Position 1 false identifications which were followed by a correct response, F (2, 90) = 38.91, $p < .01$, and the amount of familiarization differentially affected *S*s receiving different types of PA lists, F (2, 90) = 16.85, $p < .01$. These findings further indicate that the amount of stimulus-only familiarization did affect the encoding during PA learning.

A consideration of the responses to the original stimuli provides for an assessment of recall as a function of recognition performance. The number of correct identifications (CIs) regardless of whether they were accompanied by the correct PA-response terms was compared with the number of CIs that were followed by elicitations of correct response terms from

the PA list (CI–CR). This within-*Ss* factor was combined with 3 between-*Ss* comparisons of the integration level, familiarization, and appropriateness variables. Overall, the design was a 2 × 2 × 3 factorial arrangement. Table 3 shows these conditions and corresponding performance levels. Of the between-*Ss* sources of variance, the integration level and appropriateness factors yielded statistically reliable differences, $F\ (1, 180) = 8.02$ and $F\ (2, 180) = 9.03$, respectively, $ps < .01$. The familiarity variable and Integration Level × Appropriateness interaction approached reliability, $F\ (1, 180) = 3.82$ and 3.28, respectively, $ps < .10$. The reliable within-*Ss* variable of CI vs. CI–CR, $F\ (1, 180) = 120.00$, $p < .01$, and CI vs. CI–CR × Appropriateness interaction, $F\ (2, 180) = 26.96$, $p < .01$, indicate that given stimulus recognition, *Ss* still had trouble recalling the responses, and the recall difficulty depended upon the PA condition. No other factors or interactions produced *F*s greater than unity.

TABLE 3

MEAN NUMBER OF CORRECT IDENTIFICATIONS (CI) AND MEAN NUMBER OF CIs FOLLOWED BY A CORRECT RESPONSE (CI–CR) IN PHASE 4 AS A FUNCTION OF INTEGRATION LEVEL, NUMBER OF PRIOR FAMILIARIZATION TRIALS, AND PAIRED-ASSOCIATE CONDITION

Familiarization trials and paired-associate condition	Low integration		High integration	
	CI	CI–CR	CI	CI–CR

DISCUSSION

Taking all phases into account, the following conclusions emerge: (*a*) The error data indicate that nonrecall stimulus familiarization of unintegrated stimuli does lead to changes in the selective encoding of the familiarized items from rectilinearity to an ordering consistent with information analyses of words (first, last, second, in order of decreasing dominance). (*b*) There seems to be little evidence of a shift in encoding integrated stimuli as a result of familiarization, although any shift would appear to be away from first, last, middle, and in the direction of serial processing. (*c*) Familiarization results in an overall increase in the number of correct recognitions and a decrease in the number of false recognitions for both integrated and unintegrated stimuli. (*d*) Although familiarization induced encoding changes do occur, they appear to have little effect on the *rate* of PA learning. (*e*) A stimulated-recall task given after PA learning indicated that although 1 and 10 trials of familiarization lead to the same rate of obtaining correct responses in PA, the type of encoding may be quite different for unintegrated stimuli. The implications of the present findings for the stimulus encoding variability hypothesis will be considered below.

The data from Phase 2 indicated that for unintegrated stimuli a shift in the encoding PDF occurs during nonrecall familiarization, even though there would appear to be no "reasons" for this to happen. In fact, given the simple instructions to read the items, it is unlikely that *Ss* did not suspect a second task such as recalling the items they had read. Since this type of *S* hypothesis should have led to rectilinear PDFs, the reliable shift to first-position dominant occurred in spite of this potential problem. The finding of an altered PDF as a consequence of stimulus-only familiarization is clearly contrary to conclusions reached by Martin (1968). Although it is important to note that he was explicitly talking about familiarization procedures which altered stimulus availability in the sense of recallability, there can be little doubt that in the present study the familiarization variable would have produced differences in stimulus recall had such a measure been taken. However, in order to assess this assumption directly, 4 groups of 16 *Ss* each were administered the familiarization task, and then asked to recall the items. The obtained recall means were 1.50, 3.50, 4.31, and 5.00, for the low-1-trial, low–10-trial, high–1-trial, and high–10-trial groups, respectively. As can be seen, the familiarization task employed herein was effective in altering stimulus availability in the sense of recallability. Furthermore, the means for the recall task directly parallel those obtained with the recognition procedure. Thus, although it appears counterintuitive,

the present findings suggest that mere repetition of nonintegrated verbal items results in a shift in the PDF for letter encodings toward first-position dominance.

The obtained focusing on the first-position-letter encoding for the low–10-trial groups was expected to facilitate PA learning for the S groups as compared to the respective low–1-trial group. That the facilitation was not obtained for the low-integrated S comparison was probably due to a ceiling effect as further evidenced by the lack of difference between any of the low- and high-integration S groups on the PA learning task. However, equivalent rates of PA acquisition after varying levels of stimulus familiarization should not be taken to indicate that familiarization does not affect stimulus processing during PA learning, as has previously been concluded by Martin (1968). The Phase 4 stimulated-recall data from the present experiment indicated that the low–1-trial S group poorly discriminated between original stimuli and distractors which had first letters in common with these stimuli. Contrarily, the analogous 10-trial group rarely made this type of error, but rather performed very much like the high-integrated S groups in that these *S*s were not only able to identify the original stimuli, but also most often correctly identified the distractors and gave a response which would have been correct on the basis of the first letter. The percentages for these contingencies were 23.12, 64.38, 50.00, and 43.75 for the low–1- and low–10-, and high–1- and high–10-S groups, respectively. As can be seen, the low–1-trial group is substantially different from the remaining 3 groups. This indicates the low–10-trial S group knew the relationship between the stimuli and responses (first letters identical), and also knew something about the entire stimulus items. Contrarily, the low–1-trial S groups apparently knew little about the stimulus items except the first letters. In terms of the hypothesis advanced by Martin (1968), these data imply that for low-integrated items the PDF degenerated toward a single encoding with increased familiarization, and may have become platykurtic more rapidly during PA learning than is the case with little or no familiarization. Hence, it is suggested that the effect of nonrecall stimulus familiarization may be either to speed up the encoding phase during PA learning, or to allow a considerable portion of this phase to occur prior (and transfer) to the PA task. Of these, the latter seems more appealing at present.

Although greater familiarization of low-integrated items was expected to lead to increased interference within the S, cond[illegible] in the opposite direction [illegible] lack of increase in interf[illegible] occurred as a result of a domin[illegible] encoding leading to a more ra[illegible] of the interference and a compen[illegible] in encoding. However, it seems [illegible] this type of shift occurs. Williams[illegible] wood (1970) have reported that [illegible] spontaneously shift encodings away fr[illegible] position to avoid interference, at least [illegible] 2-list situation. However, the trend fo[illegible] creased interference in the low-integrated condition with increased familiarization wo[illegible] be consistent with the hypothesis that wi[illegible] increased familiarization, the encoding PDF may become platykurtic more rapidly during a PA task. This would also tend to reduce interference due to re-paired stimulus and response first letters. The trend for increased familiarization of high-integrated stimuli to lead to increased interference is a puzzling one.

Throughout this report, the emphasis has been on the distribution of encodings isomorphic with the letter components. This is, of course, an exceedingly limited view. Other plausible encodings would include 2-letter combinations as well as an encoding of a unitized version of the item. Within this context, one could consider all of the items presented on the stimulus recognition trials to constitute tests of encodings. The 3 types of distractor items would be assumed to test for individual letter selection, or at least letter dominance, and the original items as tests of stimulus integration encodings. Unfortunately, the latter is confounded, as a correct recognition of an original item could be based on single-letter encodings, 2-letter combination encodings, or encodings based on all 3 letters. Nevertheless, this confounding can be made somewhat less ambiguous by the following analysis. If familiarization results in only a shift to single-letter encodings based on the first position for low-integration materials, then one might expect not only an overall increase in the number of correct recognitions of original stimuli (as was obtained) but also an increase in the number of false recognitions to distractors having first-position letters identical to the original stimuli (the opposite was obtained). Familiarization resulted in an increase in the *proportion* of false identifications of Position 1 distractors but a decrease in the overall number of correct identifications.

This finding would be anticipated if the PDF for the various encodings was assumed to shift from some initial distribution to a dominance of a single encoding, and finally to an integrated version of the nominal stimulus as learning processed during familiarization training. If the rate of these encoding changes was less than uniform for all items, the higher level of familiarization would be expected to result in more correct identifications and fewer errors; but given an error, they would be primarily those indicating first-position encodings, as was obtained. Although the Phase 2 data indicated changes in the distributions of encodings, the rate of PA acquisition obtained in Phase 3 was not a function of the amount of prior stimulus-only familiarization. Nevertheless, the Phase 4 recognition data clearly indicate that the shift in the PDF for the various encodings resulting from stimulus-only familiarization did transfer to the PA task, and in such a way as to alter the availability with which the alternative encodings could enter into overt-response-producing associations.

PERIPHERAL VISION LOCATION AND KINDS OF COMPLEX PROCESSING

DAVID C. EDWARDS[1] AND PAULA A. GOOLKASIAN

Iowa State University

Processing capacity in the visual periphery was tested with 4 kinds of tasks: (*a*) detection of light onset, (*b*) recognition of the position of a U-shaped figure, (*c*) identification of a letter, and (*d*) categorization of 3-letter words. These tasks were presented at 2 luminances, 3 sizes, and 3 stimulus durations at distances from the fovea (10°, 15°, 25°, and 58°) at which retinal structures differ. In the near periphery, 10°, performance under optimal conditions was good for all tasks. At 15° information concerning detection, recognition, and identification was handled with a high degree of accuracy; however, the classification task was performed at a level just above chance. The processing capacity in the far periphery, 25°, was good only for detection judgments. At 58°, extreme periphery, the detection task was the only task performed above chance. Of the state variables, size had an important effect at all locations, but brightness and stimulus duration had minimal effects. Response time measures gave supporting evidence for the accuracy of response data.

Conceptions of peripheral vision have come from studies of acuity (e.g., Kerr, 1971; Low, 1943, 1947; Mandelbaum & Sloan, 1947; Wertheim, 1894), visual search (e.g., Mackworth & Morandi, 1967; Williams, 1966; Yarbus, 1967), and descriptions of the kinds of processing limits upon peripherally received stimulation (Engel, 1971; Leibowitz, Johnson, & Isabelle, 1972; Mackworth, 1965; Menzer & Thurmond, 1970; Newsome, 1972; Payne, 1967; Sanders, 1970).

The salient fact of peripheral vision has been the marked effect on measures of acuity. The dominance of the acuity effect has inhibited study of other kinds of capabilities and limits of peripheral vision. There have been only a few writers who have accepted the acuity facts and continued to ask questions of the role of peripheral vision. According to Gibson (1966), the periphery functions to guide the fovea: "Interesting structures in the array, and interesting bits of structure, particularly motion, draw the fovea toward them, [p. 360]." In this context, stimulation reaching the periphery is presumed to be processed as a locus of concentration of information within a visual display, but the information itself is not fully analyzed. Mackworth and Morandi (1967) presented data that supplement Gibson's notion. They found a greater number of fixations in the regions of the pictures that contain unpredictable contours or unusual information. Thus the amount of information in each locus determined the adjustments of the eye. Peripheral vision in their account processes predictable and redundant information. They further relied on Hubel and Wiesel (1965) for physiological evidence to suggest that there is a rapid processing in the periphery of straight lines and slightly curved boundaries. Mackworth and Morandi summarized the nature of the visual mechanism by writing " . . . the peripheral retina therefore quickly screens off the predictable features and leaves the fovea to process the unpredictable and unusual stimuli [1967, p. 551]."

These notions suggests a processing dichotomy in the visual system: fovea vs. periphery. Yet attempts at empirically mapping the processing ability of the periphery do not support that notion. The classical acuity functions based on Landolt ring discrimination have shown performance to decrease rapidly from the fovea to 5° with a slower decline in performance over the remaining area (e.g., Wertheim, 1894). Sanders (1963) offered specifications for

functionally different areas within the visual field based on a light discrimination task. Following a performance curve[2] that deviated from a linear function of visual angle at 2 points, at the region of 20°–25° from the fovea and at 80°, he formulated a tripartite system of the visual field. In the stationary field, particularly the area extending from the fovea to 20°–25°, incoming signals are grouped and processed by foveal and peripheral vision. The eye field uses eye movements to handle information in the area out to 80°. The eye field processes in some form between grouping and successive handling of signals. The head field includes the area beyond 80° and treats incoming signals successively using both head and eye movements. The importance of Sanders' distinction lies not in its delineation of specific peripheral fields but rather in its theoretical movement away from describing the visual system as strictly peripheral vs. foveal and in its investigation of processing types within the periphery itself. Polyak's (1941) careful summary of the change in retinal structure through the periphery provides another consideration for assuming a continuous or at least multiple-staged retina.

The studies described below are an exploratory attempt at comparing different processing tasks at several locations in the periphery. Variables of luminance, size, and duration make up a matrix of state conditions to attempt to locate effective variables for peripheral processing. There are 4 studies and each compares 4 tasks at 2 luminances, 3 stimulus sizes, and 3 exposure durations. Since the experiments differ only in peripheral location and *S*s, they are reported together. The results can be examined for evidence of the maximum processing capacity at each location and also of the extent to which state variables affect performance.

Method

A within-*S*s factorial design was applied to separate groups of 10 *S*s at each of 4 peripheral angles: 10° (the foveal edge of the near periphery), 15° (the foveal edge of the middle periphery), 25° (the foveal edge of the far periphery), and 58° (the foveal edge of the extreme periphery). It was assumed that these locations would best represent 4 peripheral regions distinguished neurologically by Polyak (1941). The 4 stimulus tasks used were presumed to vary in processing complexity. These were (*a*) detection of a lighted line segment, (*b*) recognition of the position of a U-shaped figure, (*c*) identification of a letter, and (*d*) categorization of 3-letter words. Three exposure durations, 3 stimulus sizes (distances), and 2 stimulus luminances completed the design. The tasks were given on successive days in the above order to all *S*s.

Apparatus. The visual tasks were presented by alphanumeric electroluminescent displays in which elements were separately programmed. The light detection task consisted of one lighted segment of the display measuring 4.75 × 34.90 mm. The stimuli of the recognition task were U-shaped figures measuring 25.40 × 34.90 mm. and appearing in one of 4 positions: upright, inverted, opening to the right, and opening to the left. The stimuli of the identification task were the letters H, L, O, and X, 50.8 mm. high and 34.9 mm. wide. The categorizing task used 3 adjacent displays to present a 3-letter word, 50.8 mm. high and 162.4 mm. wide. The words belonged to one of 4 categories: animals, part of body, proper names, and utensils.

The 3 exposure durations were 200, 600, and 1,000 msec. Stimulus size was varied by placing the display at 1.83, 2.74, or 3.66 m. from *S*'s eye. The luminance of the lighted elements was 3.9 cd/m² or .043 cd/m² upon a black background of .0017 cd/m², measured by Spectra brightness spot meter, model UB 1½°.

The fixation point was an illuminated (.48 cd/m²) ball, 3.81 mm. in diameter, 150 mm. above the center of the display, displaced to one side so as to make the experimental angles of 10°, 15°, 25°, or 58°. The *S*s were seated in an adjustable chair enabling easy control over the distance between *S*'s eye, the fixation point, and the displays. The chair also provided a brace against which *S* could restrict head movements. A black eye patch was always placed on the right eye, and the displays were presented to the temporal visual field of the left eye.

The *S*, holding a response box containing 4 buttons, indicated the response by depressing the appropriate button. This also provided a response time measure. An association between the stimulus alternatives and the position of the buttons was formed during the practice trials for each task.

Electrooculograms were recorded from Beckman Biopotential electrodes 4 mm. in diameter affixed to the skin about 5 mm. to the temporal side of each eye. The Beckman Dynograph recording provided a record assuring that *S* made no saccades greater than 5° at the time of each stimulus presentation.

Subjects. The *S*s were 40 men and women student volunteers who were given credit towards their general psychology course grade. They all had

[2] These measures were taken on a binocular visual field whereas most of the Landolt ring studies were performed using a monocular field.

normal vision in their left eye without glasses or contact lenses. The *S*s were randomly assigned to each of the 4 peripheral locations. Apparatus design dictated that the 5 *S*s run on any 1 day belong to the same group.

Procedure. Each *S* was given one of the 4 tasks in daily test sessions of 1 hr. Within each 144-trial test session, the stimuli were presented a total of 8 trials at each factorial combination of size, brightness, and exposure duration. The presentation order was counterbalanced across *S*s for the size of the stimulus (half of the *S*s received the sequence at distances of 1.83, 2.74, and 3.66 m. and the others in the reverse order), and the presentation order of each brightness and exposure duration was random within each size level.

The *S*s were visually familiarized with the stimulus forms and given at least 15 practice trials with feedback. However, in the word categorization task, they were given verbal examples of possible members of the 4 categories and then given 15 practice trials with feedback.

The *S*s were instructed to fixate their eye on the illuminated ball, focus their attention to the periphery, and press the appropriate button as soon as they detected the stimulus. Any *S* found by the electrooculograph to have moved his eye fixation during stimulus exposure was removed from the experiment. Feedback as to the correctness of the response was not given during the experimental session.

Results

A separate analysis was made for each angle and for each dependent measure: number of correct responses and response time. A factorial design was used having *S*s as the only random factor (3 levels of size × 2 levels of brightness × 3 exposure durations × 4 tasks × 10 *S*s). The magnitude of the experimental effects was expressed as ω^2, indicating the ratio of that variance component to the sum of the variance components of that factor and its error term (see Hays, 1963; and Vaughan & Corballis, 1969). The main effects of all 4 experiments (angles) are presented in Table 1 (number correct) and Table 2 (response time).

10° visual angle. Performance in the near periphery at 10° was high for the 4 tasks. For the detection task (Task 1), the *S*s made 100% correct judgment. They were 77% correct on the recognition task (Task 2), 79% correct on the identification task (Task 3), and 41% correct on the classification task (Task 4). The strongest of the factors was due to tasks, accounting for 48% of the variance, $F\ (3, 27) = 82.54$, $p < .005$, $\omega^2 = .48$. Performance levels among the tasks were in the expected direction; however, Tasks 2 and 3 did not differ significantly, $F > 1$. Tasks differences interacted significantly with size, $F\ (6, 54) = 14.63$, $p < .005$, $\omega^2 = .04$, and brightness, $F\ (3, 27) = 19.66$, $p < .005$, $\omega^2 = .01$, but these interactions are probably due to ceiling effects in Task 1 and possible floor effects on the measure in Task 4.

Of the 3 presentation variables, stimulus size (distance) appeared to have the greatest effect, $F\ (2, 18) = 70.17$, $p < .005$, $\omega^2 = .12$. Brightness was not a strong factor, $F\ (1, 9) = 62.28$, $p < .005$, $\omega^2 = .02$, but it did interact with stimulus size, $F\ (2, 18) = 16.63$, $p < .005$, $\omega^2 = .01$, so that brightness had a greater effect at smaller display sizes. Finally, although performance increased with longer exposure durations, $F\ (2, 18) = 4.45$, $p < .05$, $\omega^2 = 0.00$, it accounted for a negligible amount of variance.

The analysis of response times supported the findings with number of correct responses. The mean response time increased with the complexity, judged by *E*, of the processing task: .63, 1.29, 1.63, and 2.36

sec., F (3, 27) = 40.58, $p < .005$, $\omega^2 = .59$. Again there was no significant difference between Tasks 2 and 3, $F > 1$. Exposure duration was positively related to response time, F (2, 18) = 16.77, $p < .005$, $\omega^2 = .01$. Levels of brightness, F (1, 9) = 9.23, $p < .025$, $\omega^2 = .01$, and size, F (2, 18) = 25.22, $p < .005$, $\omega^2 = .04$, were inversely related to response time. These latter findings were consistent across the first 3 tasks. The fact that response time did not increase with a decrease in size or a decrease in intensity of the display in the classification task indicates that the *S*s had perhaps lost confidence in their ability to perform the task. That explanation perhaps also accounts for the significant Task × Exposure interaction, F (6, 54) = 7.68, $p < .005$, $\omega^2 = 0.00$, Task × Brightness interaction, F (3, 27) = 8.50, $p < .005$, $\omega^2 = 0.00$, and Task × Size interaction, F (6, 54) = 8.51, $p < .005$, $\omega^2 = .03$.

15° visual angle. In the middle periphery, 15°, accuracy of processing was high for the first 3 tasks, 91%, 52%, and 57%, but low for the classification task, 27%. Some decrement in performance at 15° may be attributed to the blind spot. The strongest factor was task differences. Performance was inversely related to task complexity, F (3, 27) = 79.79, $p < .005$, $\omega^2 = .48$, although Tasks 2 and 3 did not differ, $F > 1$. Size, F (2, 18) = 88.47, $p < .005$, $\omega^2 = .14$, accounted for a greater portion of the variance than did brightness, F (1, 9) = 23.18, $p < .005$, $\omega^2 = .01$, and exposure duration was not a significant effect, F (2, 18) = 1.69. Size and task again interacted, F (6, 54) = 10.41, $p < .005$, $\omega^2 = .06$, as did task and brightness, F (3, 27) = 3.79, $p < .025$, $\omega^2 = 0.00$. Both of those interactions are probably an artifact of a ceiling effect on the response measure in Task 1 and a floor effect in Tasks 3 and 4. The response time data were consistent with those from 10°. Mean response time increased with task complexity: .76, 1.56, 1.76, and 2.37 sec., F (3, 27) = 23.76, $p < .005$, $\omega^2 = .39$. Response time was positively related to exposure duration, F (2, 18) = 13.85 $p < .005$, $\omega^2 = .01$, and was inversely related to size, F (2, 18) = 5.84, $p < .025$, $\omega^2 = .01$. A lack of consistency in effects was noted in the response times for Task 4 as compared to those from the other tasks. Again, this was probably due to *S*'s confidence that he could perform the task. That also explains the Size × Task interaction, F (6, 54) = 7.21, $p < .005$, $\omega^2 = .03$.

TABLE 2

MEAN RESPONSE TIME

Conditions	Visual angles			
	10°	15°	25°	58°
Task				
1	.63	.76	.68	.61
2	1.29	1.56	1.59	1.81
3	1.63	1.76	1.75	1.96
4	2.36	2.37	2.33	2.25
Stimulus size				
Large	1.29	1.48	1.52	1.69
Medium	1.45	1.67	1.61	1.67
Small	1.70	1.69	1.63	1.61
Stimulus brightness				
.043 cd/m²	1.55	1.58	1.57	1.63
3.9 cd/m²	1.41	1.65	1.60	1.69
Stimulus duration				
.2 sec.	1.38	1.49	1.44	1.51
.6 sec.	1.46	1.61	1.60	1.68
1.0 sec.	1.60	1.75	1.72	1.78

25° visual angle. In the far periphery, 25°, the accuracy of performance levels for the 4 tasks was 91%, 40%, 53%, and 24%. The strongest factor was again task differences, F (3, 27) = 191.52, $p < .005$, $\omega^2 = .98$, although Tasks 2 and 3 did not differ, $F > 1$. There was again a size effect, F (2, 18) = 60.6, $p < .005$, $\omega^2 = .06$, a brightness effect, F (1, 9) = 17.66, $p < .005$, $\omega^2 = .01$, a Task × Size interaction, F (6, 54) = 19.26, $p < .005$, $\omega^2 = .05$, and a Task × Brightness interaction, F (3, 27) = 11.23, $p < .005$, $\omega^2 = .01$, but each of these effects was relatively weak.

The response time data at 25° were consistent with those of the other peripheral regions. Mean response time increased with task complexity: .67, 1.59, 1.74, and 2.33 sec., F (3, 27) = 61.47, $p < .005$, $\omega^2 = .64$. Again response time was found to

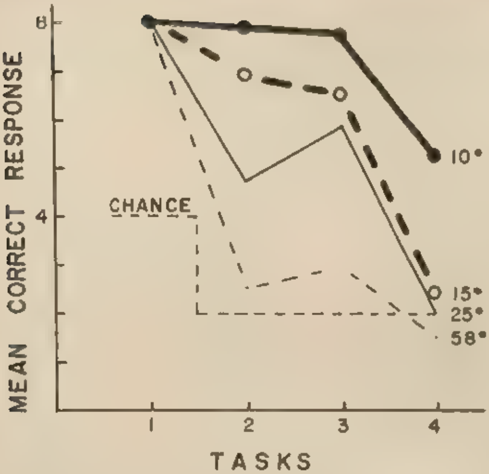

FIGURE 1. Selected mean performance to reflect the optimal (best) performance on each task at each angle; the points are comparable only in that sense.

be positively related to exposure duration, $F\ (2, 18) = 30.07$, $p < .005$, $\omega^2 = .02$, and negatively related to the size of the stimulus, $F\ (2, 18) = 4.73$, $p < .025$, $\omega^2 = 0.00$. Variability was again evident within response time in the fourth task, and as before this is likely accounted for by chance performance levels of the *S*s under all experimental conditions. As in the more nearly foveal groups it explains the interactions of task and size, $F\ (6, 54) = 4.95$, $p < .005$, $\omega^2 = .01$, task and exposure duration, $F\ (6, 54) = 6.50$, $p < .005$, $\omega^2 = 0.00$, and task and brightness, $F\ (3, 27) = 5.99$, $p < .005$, $\omega^2 = .01$.

58° visual angle. Performance in the extreme periphery, 58°, even under optimal conditions was low except for simple light detection in Task 1. The best performances were 100%, 26%, 31%, and 19%. Task, $F\ (3, 27) = 1{,}222.09$, $p < .005$, $\omega^2 = .99$, and size, $F\ (2, 18) = 7.60$, $p < .005$, $\omega^2 = 0.00$, were the only significant main effects. The Brightness × Exposure Duration, $F\ (2, 18) = 5.88$, $p < .025$, $\omega^2 = 0.00$, and Size × Task, $F\ (6, 54) = 3.66$, $p < .005$, $\omega^2 = 0.00$, interactions were also significant but with very small factor strength. These interactions are probably influenced by the Task 1 ceiling effect and Task 4 floor effect on the measure. Response time showed the usual increase with task complexity: .61, 1.81, 1.96, 2.25 sec., $F\ (3, 27) = 49.40$, $p < .005$, $\omega^2 = .53$. Response time also increased with exposure duration, $F\ (2, 18) = 21.11$, $p < .005$, $\omega^2 = .02$, and there were minor effects of size, $F\ (2, 18) = 4.64$, $p < .025$, $\omega^2 = 0.00$, Size × Brightness interaction, $F\ (2, 18) = 6.62$, $p < .01$, $\omega^2 = 0.00$, Task × Duration interaction, $F\ (6, 54) = 4.77$, $p < .005$, $\omega^2 = 0.00$, Task × Brightness interaction, $F\ (3, 27) = 6.44$, $p < .005$, $\omega^2 = 0.00$, and Size × Task interaction, $F\ (6, 54) = 2.92$, $p < .025$, $\omega^2 = .01$.

DISCUSSION

The ability of the periphery to process information depends upon the region stimulated, the complexity of the task, and the size of the stimulus. Figure 1 is a mapping of the processing accuracy at each of the 4 peripheral regions under the most optimal values of the significant factors in the experiments. In the near periphery all 4 types of information were processed, given a large, bright, and long-duration stimulus. At the middle periphery information concerning detection, recognition, and identification were handled at a high degree of accuracy, but the more complex task, classification of words, was performed only at about chance. The processing capacity in the far periphery was good only for detection judgments. It dealt with information about recognition and identification but only at a limited degree of accuracy. At 58° in the extreme periphery the only task that was performed was light detection.

Across the periphery the factor which had the strongest effect on peripheral vision, in addition to task complexity, was size of the stimulus. The effect of size is in accord with the known facts of neural anatomy, especially the distribution of rods in the periphery and their manner of connection to the bipolar and ganglionic cells. Unlike the almost one-to-one connection with the foveal cones, the bipolar cells in the periphery connect with many rods, and in turn information from a number of bipolar cells is carried to each ganglionic cell. Assuming that this simple model of structure also applies to function, a given stimulus "edge" of adjacent light and dark extents would be less likely to be processed in peripheral regions where both components strike cells that stimulate the same ganglion. In this framework one would expect size to be an increasingly important variable as angular

deviation increases. That did not occur in this experiment, probably because of floor effects upon performance at 25° and 58°.

Brightness had a significant effect on correct response performance in all regions except the extreme periphery. It was not a strong effect, however. That supports Mandelbaum and Sloan's (1947) conclusion that "light intensity is not as critical a factor in peripheral acuity as it is in central acuity [p. 587]." That was especially true with the response time measure where brightness did not have an effect after 10°.

Exposure duration increased the accuracy of performance only in the near periphery, but it did have a significant effect upon response time. As is commonly found, the longer that the *S*s had to view the stimulus, the longer they took to respond. Aside from the near periphery, however, exposure duration did not affect the level of performance.

One of the most valuable contributions of this study is its demonstration that parts of the periphery, specifically the near and middle periphery, are capable of performing more complex types of processing than the visual information theories of Gibson (1966), Mackworth (Mackworth & Morandi, 1967), and others usually ascribe to them. Perhaps instead of talking of the visual system as dichotomous in nature, our notion should be extended to 3 or more areas based upon processing capacities with no sharp dividing line between them. The first area would be the fovea, extending to perhaps 2½°. The second area would extend from just outside the fovea up to and perhaps through the near periphery at 15°. With practice in attending in the periphery, an *S* could here handle information leading to judgments of identification or classification. The third area would include the middle periphery from about 15° to about 25°, and this region appears to have a limited ability at processing complex information. The fourther is the remaining peripheral region, which may have only the crude and primitive processing capacity of which Gibson and Mackworth write.

REACTION TIME TO PHONEME TARGETS AS A FUNCTION OF RHYTHMIC CUES IN CONTINUOUS SPEECH [1]

JOYCE L. SHIELDS [2]

U.S. Army Research Institute for the Behavioral and Social Sciences, Arlington, Virginia

ASTRID McHUGH AND JAMES G. MARTIN

University of Maryland

Two experiments using the same *Ss* in one sitting tested the hypothesis that the temporal redundancy inherent in rhythmically structured sound sequences is used during listening by the perceptual mechanism. Reaction times (RTs) were recorded for *Ss* who responded to the target phoneme /b/ in running speech. In the main experiment sentences containing the target phoneme as the word initial phoneme in either accented or unaccented syllables were presented to listeners. In the control experiment the words containing the target phoneme were spliced out of the sentence context and embedded in a string of nonsense words and presented to the same *Ss*. The RTs to the target phoneme were faster to accented than to unaccented targets in the sentence context, whereas RTs did not differ significantly in the nonsense sequence context. These results indicate that RT cannot be explained by simple differences in articulatory and other characteristics between accented and unaccented targets, and that temporal redundancy is a determining factor in RT to targets in connected speech. Accented targets are temporally predictable whereas unaccented targets are not.

Consideration of the rhythmic movement involved in serial behaviors led Lashley (1951) to propose a general timing mechanism underlying all natural movement sequences. Rhythmic action and hierarchical motor organization were suggested to be related concepts which might provide the natural link between the perception and production of all integrated movements, including speech. The details of such a relationship were not made clear at that time, although the need for methods to analyze such systems was emphasized. Recently, Martin (1972) has offered 2 rules for the formal description of simple natural rhythmic patterns, and has shown how rhythmic action has consequences for theories of motor and perceptual behavior in real time. The general thesis developed by Martin suggests that the organization of speech sequences as well as all natural movement sequences are constrained by relative timing (i.e., rhythm).

Martin (1972) hypothesizes that speech elements are hierarchically organized in a coherent, internal temporal structure at the sound level. That is, the locus of each sound element along the time dimension is determined relative to the locus of all other elements in the sequence, adjacent and nonadjacent. The sequence is naturally constrained by the underlying temporal organization. An alternative to this viewpoint suggests that speech elements are simply ordered in a successive (concatenated) sequence. According to the concatenation view the relationship between elements at the sound level is that of

ordering, without regard to their structural relationships or organization at some other level. These alternatives, rhythmic patterning and concatenation, are related to distinct theoretical points of view concerning real-time behavior, and they have distinct implications for the perception and production of speech. The production of rhythmic speech patterns requires temporal patterning between adjacent and nonadjacent speech sounds, whereas the concatenative alternative requires only correct temporal sequence. These alternative viewpoints make distinctly different predictions about the degree of organization in speech sounds and in their perception. The rhythmic viewpoint suggests that certain elements in a speech sequence should be more predictable in time than others, whereas the concatenative viewpoint would appear to suggest that each speech element is equally predictable (or better, equally unpredictable) in time. The hypothesis generated by the rhythmic theory will be developed in the following.

Rhythmic patterns are element sequences in which some elements are accented, standing out to some degree, whereas other elements are not. The main implications of the rhythm rules stated by Martin (1972) are (*a*) accent level covaries with timing, and (*b*) main accents remain equidistant. If speech sequences are rhythmically patterned, then some of the speech elements will be accented relative to the other elements. The hierarchical organization of these temporal sequences would suggest that main accents would fall on the potentially most important elements of the speech sequence. Therefore, a logically consistent hypothesis would suggest that an efficient perceptual mechanism would make use of the information furnished by the prosodic (rhythmic) contours of the speech pattern. That is, a rhythmic pattern is temporally redundant so that once early accents are heard the location of later accents (and perhaps the end of the pattern as well) can be predicted in time. Such a perceptual mechanism would allow for the focusing of attention on the elements in the speech sequence receiving accent. The hypothesis tested in this experiment is that the temporal redundancy in the speech sequence is used by the perceptual mechanism.

Martin's (1972) theory predicts that the listener is capable of anticipating the occurrence of accented speech elements on the basis of the prosodic contours produced by the speaker. This implies that the listener's attention will be focused anticipatorily on the accented syllables (i.e., accented syllables are targets during perception). The relationship between accented syllables and relative timing is such that certain aspects of the spoken signal become temporally predictable to the listener once he has "locked in" to the pattern. Presumably the hearer's targets in listening will be the same as the targets of the speaker—namely, the accented syllables—as these are likely to be the most informative segments of the speech sequence. That is, the listener's perceptual strategy is such that during ongoing speech, it is possible for him to anticipate in real time the onset of accented targets and also the end of the speech sequence. Therefore, if he is asked to respond to a given aspect of the speech signal, for example, the initial phoneme in a syllable, his reaction time (RT) should be faster to phoneme targets in accented syllables than to phoneme targets in unaccented syllables. Since unaccented syllables are not temporally redundant with respect to the remainder of the pattern, they are not expected at any particular time.

Of course, faster RTs might also be predicted on the basis that a target phoneme in an accented syllable is not only louder, etc., but is also more clearly articulated than one in an unaccented syllable and hence should be perceived more easily. Experimental support of this point of view is provided by a study by Lieberman (1963). In that study experimental words were gated out of running speech. Lieberman found that words spoken in the context of sentences where they were informative were more easily recognized than the same words spoken in a context where they were redundant. If quality of articulation and

other characteristics of accented syllables themselves are the determining factor in RT, faster RTs would be expected to the accented target. Therefore, an experimental test of Martin's (1972) theory must demonstrate that the results cannot be explained by simple differences in articulatory and other characteristics between accented and unaccented targets.

Two separate experiments were conducted using the same set of *S*s. That is, each *S* participated first in the main experiment and then in the control experiment in one sitting. In the main experiment sentences containing the target phoneme /b/ as the word initial phoneme in accented and unaccented syllables were presented to listeners. The *S* was asked to listen for the phoneme and respond by pressing a button as rapidly as possible. In the control experiment the words containing the target phonemes had been spliced out of the running speech and embedded in a string of nonsense words, and *S* was asked to perform the same task. If temporal redundancy is a determining factor in RT, RTs to the accented targets should be faster than RTs to the unaccented targets in the sentence context, and to a greater extent than in the control experiment.

Method

Design

Each *S* served both in the main and control experiments. First he listened to a tape, which consisted of 30 sentences. His task was to press a button as quickly as possible whenever he heard the phoneme /b/ and to write down the /b/ word after the sentence ended. For the main (sentence context) experiment the design was a 2 × 3 repeated measurements design (accented or unaccented target and 3 phrase locations). For the main vs. control experiment comparison, *S* listened to 30 sequences, each consisting of 8 2-syllable nonsense words, one of which was the /b/ word, and performed the same task as for the sentences. The design was a 2 × 2 repeated measurements design (accented or unaccented target and nonsense or sentence context). There were 6 different tapes, each using the same sentence frames and nonsense sequences. All conditions were represented on each tape, but the particular target conditions and words occurred in different sentences and nonsense contexts on the different tapes.

Materials

Main experiment (sentence context). The experimental list consisted of 30 sentence frames and 30 2-syllable nonsense words which were used in the sentences in a context where a noun would normally occur. The nonsense word occurred at the beginning, middle, or end of the last phrase of each sentence. These phrases followed a natural clause break in the sentence and were approximately 7–9 syllables long. Across the 6 tapes the nonsense word occurred equally often at the beginning, middle, or end of the phrase. An example of each location follows.

Beginning. They had long decided that they were totally lost in the maze of side streets, for BENkik was a city of alleys.

Middle. You will hav[illegible]il any morning sightseeing plans, as the plane to benKIK leaves at noon.

End. First the group hiked along the side of the stream, then they forded the BENkik.

Twenty-four of the sentences had nonsense words that began with the phoneme /b/ (/b/ words). The nonsense words in the remaining 6 were distractors. The sentences were designed so that the phoneme /b/ would occur only in the target words. In the course of the experiment, it was discovered that 2 of the sentences each had another word with /b/ in it, e.g., "by," in the clause prior to the experimental phrase. Only a few *S*s responded to the accidental /b/s. These responses could be easily identified and were eliminated from the data. Because of the manner in which nonsense words and syllable accents were balanced across tapes, the accidental /b/s were balanced across conditions.

The 6 tapes were constructed using the 30 sentence frames and target words once each on any given tape. Balanced across tapes, each nonsense word occurred in all 6 conditions. Across the 6 experimental tapes each word containing a target was placed in 3 different sentence frames so that each word could occur in each phrase location—beginning, middle, and end. In each phrase location and sentence the target syllable was either accented or unaccented. For the example given above, on one tape the word Benkik would be accented on the target syllable (i.e., BENkik) and on another tape it would occur in the same context but with the target syllable unaccented (i.e., benKIK). Within each tape each of the 6 possible conditions (3 phrase locations and accented vs. unaccented) occurred 4 times with /b/ words and once each with distractors.

An experienced female reader recorded each of the 6 experimental sentence lists on 1 channel of a 2-channel tape. The sentences were read with natural emphasis and intonation. The appropriate accent for the nonsense word was marked on the typed material from which she read.[2] The record-

[2] This procedure, by drawing attention to the syllable to be accented, led the speaker to give the syllable primary accent. Thus it enhances the differences between accented and unaccented

ings were checked for pronunciation and accent by *E*s and those found inadequate were rerecorded. The reader was naive as to the theoretical basis for the experiment.

A tone was recorded on the second channel of the tapes, starting at the beginning of each phoneme target (the tone could not be heard by *S*). The tone was used to close a relay which was in series with 4 electronic timers and 4 buttons. The timers started when the tone operated the relay. Each timer was separately connected to a button and when *S* pressed the button the timer was stopped. For the purpose of recording the tone on the second channel, the beginning of the phoneme target was located by moving the tape manually back and forth across the playback head. There were probably slight variations in the alignment of tone onset and the beginning of the nonsense word, but such variations were probably randomly distributed. Two copies were made of each of the original sentence tapes (with tones). One of these copies served as the experimental tape in the main experiment.

Control experiment (nonsense word sequence). The nonsense words used as phoneme targets and the distractor nonsense words were cut out of the second copy of the sentence tapes. Thirty sequences of 7 2-syllable nonsense words were recorded by the same female reader. These words were then cut out, scrambled, and respliced so that there was no natural pattern to the sequences. Using a predetermined nonsystematic order, the 24 /b/ words and 6 distractors from the sentences were spliced into the nonsense sequences, occurring equally often as the third, fifth, or seventh item in the sequence, which now had 8 items. The tone on the second channel was included, so for a given word the timer would be started at exactly the same time in both the sentence and the nonsense context. These nonsense word sequences were used for the control experiment.

Subjects

The *S*s were 48 students from introductory psychology classes at the University of Maryland who volunteered to participate for extra credit. Eight *S*s were assigned to each of the 6 experimental tapes.

Procedure

The *S*s were tested in groups of 1–4, with *E* and *S* occupying adjoining rooms. Each *S* was seated out of direct view of the others and so that his arm and hand could rest comfortably with the preferred hand resting 3 in. in front of the response button.

General instructions outlining *S*'s task were recorded on the experimental tape and played at the beginning of the experimental session. The *S*s were told to listen for the sound "b as in boy" and to press the button as quickly as possible when they heard it. In addition, they were told to write down the word after the sentence ended. This instruction insured that *S* was attending to the sentences, and at the same time it provided a check on what he had responded to.

At the end of the taped instructions, *E* returned to the *S* room to answer questions, check hand positions, and clarify the instructions. The *S* was familiarized with the RT task through a series of 4 practice sentences, 3 of which contained a /b/ word. Each *S* listened first to the 30 sentences and afterward to the 30 sequences of nonsense words played over earphones at a comfortable listening level. The *E* recorded individual RTs for each sentence on prepared recording sheets.

targets, since if the second syllable is strongly accented, then (everything else being equal) the first (target) syllable naturally receives minimal accent according to the rhythm rule (Martin, 1972).

Results

Main Experiment (Sentence Context)

Six median RTs were obtained for each *S*, one for each Accent × Phrase Location condition. Table 1 shows the mean scores for all *S*s for these 6 conditions. A Phrase Location × Accent analysis of variance revealed that *S*s responded faster to accented targets than to unaccented targets at all phrase locations, $F(1, 47) = 49.60$, $p \leq .001$. At the 3 locations, *S*s responded more quickly the later the target appeared in the phrase, $F(2, 94) = 19.92$, $p \leq .001$. The significant main effects must be interpreted with reference to the significant interaction of phrase location and accent, $F(2, 94) = 8.00$, $p \leq .001$. Differences between pairs of means were tested by the Tukey procedure (Winer, 1971). The RTs to accented targets were significantly faster than RTs to unaccented targets in the early and middle phrase locations. For accented targets, RTs were significantly faster to targets in the middle and late

TABLE 1

phrase locations than to targets in early phrase locations. For unaccented targets, RTs were significantly faster to targets in the late phrase location than to the early or middle phrase locations.

Control Experiment (Nonsense Sequence)

Four separate median RTs were calculated for each *S* for the accented targets and unaccented targets in the sentence context and the nonsense sequence context. The mean scores for all *Ss* for these 4 conditions are shown in Table 2. An analysis of variance showed *Ss* responded faster to accented targets than to unaccented targets, F (1, 47) = 21.28, $p \leq .001$, and faster to targets in the sentence context, F (1, 47) = 34.10, $p \leq .001$, than in the nonsense sequence context. In addition, there was a significant Context and Accent Conditions interaction, F (1, 47) = 5.80, $p \leq .025$. Tests of the individual mean comparisons by the Tukey procedure (Winer, 1971) indicated that the sentence context RTs were shorter when the targets were accented than when the targets were unaccented. But when these same targets were spliced out of the sentence context and spliced into the nonsense word sequences, the differences in RTs to accented and unaccented target phonemes were not significant.

DISCUSSION

The results obtained in the present study suggest that the listener uses the rhythmic ...ttern of speech to anticipate accented ... in the speech sequence. The most ...nt comparison in support of such an interpretation concerns the target locations in the sentence context. In the sentence context the sharp drop in RT to accented targets in the middle location as shown in Table 1 is to be expected on the theory that some minimal temporal context (e.g., 2 "beats") must occur to establish the rhythm of a sequence. Only then do the anticipatory consequences of temporal redundancy become useful to the listener. That is, the listener's attention is focused on the primary accents in the sequence and therefore RTs to targets occurring coincident with the primary accent would be expected to be faster than to those targets which do not receive primary accent. For the unaccented syllables, the listener's attention will focus more strongly on the accented syllable which follows and it should take him longer to recognize the target in the unaccented syllable. Note that this does not imply that the listener is aware of the temporal redundancy or is capable of making deliberate use of it, as the reader can check by listening momentarily to someone speaking in the hallway. Rather, the argument here is that since syntactic and semantic context (redundancy) is ruled out, the results of the experiment can be taken as evidence that the postulated temporal redundancy exists in natural running speech.

However, in the light of the above argument, it would be predicted that RTs to accented targets should improve toward the end of the phrase, but why should RTs to unaccented targets also improve? On the present th... rhythmic patterns, here phrases, are ho... internally organized units so that the listener can anticipate the end of the unit without a terminal cue. Hence, the faster RTs at the terminal phrase locations may be due, in part, to anticipatory guessing based on rhythmic cues. Redundancy due to temporal as well as other factors makes the targets more predictable toward the end of the sentence. Support for this interpretation comes from other published work. Several phoneme-monitoring experiments (Cairns & Foss, 1971; Foss, 1969; Foss & Lynch, 1969; Hakes, 1972; Hakes & Cairns, 1970; Hakes & Foss, 1970) were run to show that latency differences depended upon differential difficulty levels in the processing of linguistic inputs. However, with the exception of one early experiment (Foss, 1969), in all studies where early and late phoneme positions were contrasted, RTs to the phoneme in the late position were found to be faster than to the phoneme in the earlier

position, which is in agreement with the results obtained in the present study, and at variance with the hypothesis that the burden on short-term memory increases as processing proceeds [illegible]

In addition, the differences observed in the present study cannot be explained by theories of linguistic complexity, since the sentence contexts were the same for accented and unaccented syllables. Therefore, differences in monitoring must be due to differences at the [illegible]tic level. These differences must be more than differences in articulation of the target phoneme since the differences between accented and unaccented syllables were nonsignificant in the nonsense sequence context. It is consistent with the present results to hypothesize that much that has been left unexplained by theories of linguistic complexity may be clarified on the grounds of temporal patterning.

Concerning the comparison between sentences and nonsense sequence contexts, when a word beginning with an accented target phoneme was spoken in the rhythmical context of the sentence the listener's RTs were significantly faster than when the same word occurred in a nonsense word sequence. In the rhythmic context of the sentence, Ss were able to respond more quickly to the accented targets than to the unaccented targets. Yet when exactly the same acoustic signal was spliced out of the sentence context and placed among other isolated nonsense words, accented and unaccented target phonemes did not produce significant differences in RT. It would appear that the rhythmic context of the sentence increased the predictability of the accented target phonemes. The differences in RTs when the targets were in the sentence context vs. the list of nonsense words cannot [illegible] word itself, since the words were spliced out of the sentence and embedded in the nonsense word context. While quality of articulation may be a factor in RT, the acoustic signal was [illegible]

In the nonsense sequence there is no rhythm[illegible] context the listener can use to anticipa[illegible] accented targets, so attention cannot be focused in advance on the accented target. Hence, the advantage of the accented over unaccented targets diminishes and the u[illegible] predictability results in generally longer R[illegible]

EFFECTS OF BASELINE SELF-REINFORCEMENT BEHAVIOR AND TRAINING LEVEL ON POSTTRAINING SELF-REINFORCEMENT BEHAVIOR

ALBERT KOZMA[1]

Memorial University of Newfoundland, St. John's, Newfoundland, Canada

PAMELA EASTERBROOK

University of New Brunswick, Fredericton, New Brunswick, Canada

The present investigation evaluated the effects of baseline self-reinforcement scores and level of training on posttraining self-reinforcement behavior. The *S*s were classified as high, medium, or low self-reinforcers on a pretraining task. An equal number of *S*s from each baseline grouping were assigned to one of 3 training levels and trained to 40%, 60%, or 80% criteria on a 4-choice discrimination learning task. The training phase was followed by a posttraining phase during which rates of self-reinforcement behavior were assessed. Results showed that training raised baseline self-reinforcement behavior only if level of training exceeded baseline self-reinforcement rates. Moreover, the 3 baseline groupings differed in the number of correct and incorrect application of self-reinforcement scores.

In recent years, considerable effort has been exerted in an attempt to isolate the variables affecting self-reinforcement (SR) behavior (Bandura & Whalen, 1966; Haynes & Kanfer, 1971; Skinner, 1953). Investigators using the directed learning paradigm to assess SR behavior have frequently concluded that *S*s tend to match SR rates at which external feedback had been provided during training Kanfer & Duerfeldt, 1967; Kanfer & Marston, 1963). A closer inspection of the literature strongly indicates that such a conclusion is an oversimplification. In studies in which the level of training was *low* (where the criterion level was less than 5 correct responses in 10 trials on the last block of training trials, or where noncontingent reinforcement was administered on fewer than 50% of the training trials), SR scores during the test phase *exceeded* training levels (Bartol & Duerfeldt, 1970; Kanfer & Marston, 1963; Marston, 1969).

These data suggest that increases in SR behavior will occur only if training rates exceed baseline SR scores. One of the aims of the current investigation was to test the preceding conclusion.

A second aim of the current investigation was to determine whether a sufficiently low training level would significantly lower the number of SR responses of high baseline (HB) *S*s. In the one relevant study reported in the literature (Bartol & Duerfeldt, 1970), a low training level had no effect on the somewhat higher SR baseline rate.

A third concern of the present investigation was to determine whether an SR change following training is indiscriminate, or whether it involves an increase in the accuracy of SR/CSR (self-reinforcement on correct choices) matching. If SR responses become highly correlated with correct choices as a result of training, SR rates may merely reflect the degree of certainty *S* has in the accuracy of his choice, rather than reflecting some nebulous internal motivating state.

METHOD

Subjects. The *S*s were 45 male and 45 female introductory psychology students attending Memorial University of Newfoundland. Each *S* was paid $1.00 per half hour of experimental participation.

Apparatus and materials. Sixty 24 × 36 mm. slides, each showing a consonant–vowel–consonant nonsense syllable in every quadrant, were used as task stimuli. The 60 slides constituted 6 copies of 10 basic slides. The association values of the nonsense syllables were 49%–51% (Archer, 1960). The type of syllable, its position on the slide, and the order of slide presentation were randomly determined.

[1] Requests for reprints should be sent to A. Kozma, Department of Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

Stimuli were presented with a Kodak Carousel 800 slide projector and covered an area of 17.8 × 27.9 cm. on the screen. The 43.2 × 25.4 × 7.6 cm. response panel had 4 toggle switches mounted along its base on S's side. The switches, numbered 1, 2, 3, and 4, represented the 4 different quadrants of the projected image. A diagram above each switch denoted the relevant quadrant. A red SR button was centered above the switches, and a white reinforcement light (lamp size 1892) activated by the SR button was mounted above it. The E's side of the panel was identical to S's side, except that 4 differently colored indicator lights replaced the 4 toggle switches. To control the 4-sec. exposure time, the 4-sec. response interval, and the 10-sec. interlock interval, BRS logic units were used.

Design and procedure. An equal number of HB, medium baseline (MB), and low baseline (LB) self-reinforcers of both sexes received 40%, 60%, or 80% task contingent training. This procedure resulted in 18 treatment cells of 5 Ss per cell.

The experiment involved 3 distinct phases—baseline, training, and posttraining or test phases. Immediately preceding the baseline phase, Ss were shown their side of the response panel. They were presented with the 4-choice discrimination task, and instructed to select the correct syllable by pressing the switch which corresponded to the quadrant in which their choice was located. The task was presented as a forced-choice task, and Ss were required to give their best choice on every trial, even if that choice was only a guess. In addition, Ss were asked to press the SR button whenever they thought that their selection of a nonsense syllable had been correct. All Ss received 3 demonstration trials to familiarize themselves with the equipment and the task.

The 3 demonstration trials were followed by the 20 trials of the baseline phase. Feedback was entirely absent during this phase, and the probability of making a correct choice was at chance level ($p = .25$). The Ss with SR scores in the upper third of the distribution were labeled HB, those with scores in the middle third were labeled MB, and those with scores in the lower third were labeled LB. The Ss with similar SR scores during the baseline phase were randomly assigned to the training conditions. Separate distributions of baseline SR scores were calculated for males and females.

Immediately following the baseline phase, Ss were instructed not to push the SR button, since E would turn on the reinforcer light every time they made a correct choice. The training phase, with feedback for correct choices, was continued until Ss reached their criterion level of 4, 6, or 8 correct choices on a block of 10 trials.

The training phase was followed by a 20-trial test phase. Before this final phase, Ss were once more asked to take over the reinforcer role and to provide their own reinforcement for correct choices by pushing the SR button.

The Ss' task responses were recorded for each

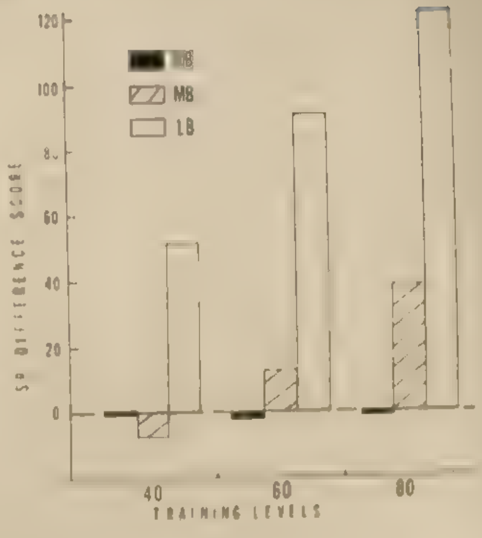

FIGURE 1. Representation of the Baseline Grouping × Training Level interaction. (SR = self-reinforcement; HB = high baseline; MB = medium baseline; LB = low baseline.)

phase of the study while, in addition, SR responses were taken during baseline and test phases.

RESULTS

The mean number of blocks of trials to criterion during training was 3.9, 6.4, and 8.9, respectively, for 40%, 60%, and 80% criterion groups. Neither baseline grouping nor sex had a differential effect on training rate.

A preliminary analysis of baseline SR scores indicated that base rates for males in the LB condition were significantly higher than for females ($p < .01$). Within each sex group, baseline SR scores did not, however, differ for 40%, 60%, and 80% training groups.

SR change. To assess the effectiveness of the different training levels in modifying SR behavior, SR change from pre- to posttraining was evaluated. The SR difference scores were analyzed by a 3 × 3 × 2 (Baseline Grouping × Training Level × Sex) analysis of variance design. Significant effects of baseline, $F(2, 72) = 78.14$, $p < .01$, training, $F(2, 72) = 13.03$, $p < .01$, and the Baseline × Training interaction, $F(4, 72) = 3.98$, $p < .01$, were obtained.

TABLE 1

MEAN BASELINE RATIO OF SELF-REINFORCEMENT (SR) RESPONSES FOLLOWING CORRECT CHOICES (CSR) TO CORRECT RESPONSES (CR) AND OF SR RESPONSES FOLLOWING INCORRECT CHOICES (ISR) TO INCORRECT CHOICES (IR), AND EXPECTED AND OBTAINED POSTTRAINING SR SCORES

Baseline		Training level											
		80%				60%				40%			
Grouping	SR score	CSR/CR	ISR/IR	SR predicted	SR obtained	CSR/CR	ISR/IR	SR predicted	SR obtained	CSR/CR	ISR/IR	SR predicted	SR obtained
High	98	.99	.90	98	96	97	.91	94	95	.97	.95	96	98
Medium	63	.93	.32	80	80*	.90	.25	64	66	.67	49	56	58
Low	13	.81	21	69	75*	.83	.40	65	61*	.51	36	[illegible]	42*

* $p < .05$ between SR baseline and posttraining scores.

An inspection of the treatment means contributing to the significant effects (Figure 1) suggests that there was little change in SR behavior of HB *Ss*, while a substantial increase in SR behavior of LB *Ss* appeared to have occurred at all training levels. Other relationships, especially the effects of training on MB *Ss*, were less clear. Accordingly, a multiple comparison of the relevant treatment groups was undertaken by means of the Newman-Keuls procedure (Winer, 1962).

Results of the comparison showed that LB *Ss* increased their SR behavior significantly more than MB and HB *Ss* after 40% and 60% training ($p < .05$). After 80% training both LB and MB *Ss* showed a significant increase over HB *Ss* ($p < .05$), with significantly greater changes occurring in the former than in the latter group ($p < .05$). Since SR difference scores for HB *Ss* do not reflect a significant pretraining–posttraining change ($p > .10$), it may be concluded that an increase in SR behavior occurred for LB *Ss* at all levels of training and for MB *Ss* only after 80% training. Training did not appear to modify SR behavior of HB *Ss* at any level. An inspection of "SR score" and "SR obtained" columns of Table 1 shows that training led to an SR change only when it exceeded SR baseline performance.

SR accuracy. A second concern of the current investigation was to determine whether increases in SR behavior were indiscriminate, or whether they reflected an increased accuracy in SR – correct response (CR) matching. To resolve the issue, postraining SR responses were divided into those which followed correct choices (CSR) and those which followed incorrect choices (ISR). The CSR/CR ratio is a good indicator of omission errors (i.e., the failure to provide self-reinforcement after making a correct response). A second type of error, the tendency to provide SR responses after incorrect choices (IR) may be represented by the ISR/IR ratio. For close SR/CR matching, CSR/CR approaches 1, and ISR/IR approaches 0.

Since HB *Ss* failed to show a significant SR change and provided self-reinforcement after virtually every response, there appeared to be little value in including them in the analysis. Both CSR/CR and ISR/IR would approach 1 (actual values: CSR/CR = .98, and ISR/IR = .92.) Training did not seem to modify SR behavior of these *Ss*.

Posttraining CSR/CR values for baseline groupings that did show an SR change with training were analyzed by a 2 × 3 × 2 (Baseline Grouping × Training Level × Sex) analysis of variance design. The only significant effects were baseline, F (1, 48) = 5.63, $p < .01$, and training, F (2, 48) = 15.53, $p < .01$. The baseline effect indicates that MB *Ss* had significantly fewer omission errors than LB *Ss* (CSR/CR = .83 and .72, respectively).

A comparison of training means showed

that the 80% and 60% groups did not differ from each other, while the 40% group differed significantly from both, $p < .05$ (CSR/CR = .87, .86, and .69, respectively). There were, thus, significantly more omission errors after 40% training than after 60% and 80% training.

Posttraining ISR/IR values were also analyzed by a $2 \times 3 \times 2$ (Baseline Grouping $\times$ Training Level $\times$ Sex) analysis of variance design. None of the effects of this analysis were significant ($p > .05$). Although commission errors did occur for MB and LB *S*s, they occurred considerably less frequently than for HB *S*s, $p < .001$ (ISR/IR = .32, .34, and .92, respectively).

The CSR/CR and ISR/IR values for baseline groupings and training levels, together with the number of SR responses predicted by these values, and the number of SR responses actually obtained, are all recorded in Table 1. The table shows that CSR/CR and ISR/IR ratios together are good predictors of SR behavior following training.

Discussion

The data on SR changes were consistent with the prediction that training modifies SR behavior whenever training level exceeds baseline SR performance. They clearly illustrate that posttraining SR rate is not solely a function of training, but is affected by *S*'s initial operant SR rate. Results strongly suggest that posttraining SR responses reflect the amount of confidence *S*s have in the accuracy of their response. The HB *S*s appeared to be extremely confident, and they did not modify their SR behavior as information about accuracy was increased by training. The approach lead to very few omissions but a large number of commission errors. On the other hand, LB *S*s, who appeared to be less confident, significantly increased their SR responses as training provided information about the accuracy of their responses. The commission errors were low during baseline performance and did not increase with training. The MB group appears to fall somewhere between the 2 extremes. Like LB *S*s, they increased the accuracy of their SR responses with training, but were not quite as cautious and had fewer omission errors. The MB *S*s were, therefore, the most accurate of the 3 baseline groupings.

The interpretation of SR responses as an expression of confidence in the accuracy of one's choice would also appear to account for sex differences in baseline SR scores. In a male-dominated society such as ours, it may be more difficult for males than for females to appear indecisive.

A comparison of current findings with those reported by Dorsey, Kanfer, and Duerfeldt (1971) points to a major difference in SR behavior if a contingent as opposed to a noncontingent feedback procedure is employed during training. While both procedures led to increases in CSRs with increases in external feedback, increases in ISRs with increases in external feedback occurred only when the noncontingent feedback technique was used. It would, therefore, appear that *S*s will provide self-reinforcement even if uncertain about the accuracy of a specific response, provided that there is a reasonable chance of being correct by guessing (under high levels of noncontingent feedback).

INDUCED CHUNKING:

TEMPORAL ASPECTS OF STORAGE AND RETRIEVAL[1]

CHARLEY McCAULEY AND GEORGE KELLAS

University of Kansas

Instructions to 3 treatment groups were to form groupings of "[illegible]ed" words via imagery, sentence formation, or repetition of unit members. A control group was given only typical free-recall instructions. [illegible] measures were employed that allowed the temporal flow of information to be monitored during both the storage and retrieval of list items. The results indicated that functional higher order units were formed in all instructed conditions and that the use of specific relational organizers differentially [illegible] the amount of encoding time required for chunk processing. A temporal analysis of retrieval revealed the presence of higher and lower order units in the recall sequences. Response times between induced chunk boundaries increased linearly across output positions in all conditions and were strongly influenced by the nature of the encoding strategy. The results are discussed in terms of several retrieval models.

An established tenet of modern theories of memory organization is that *S*s form higher order units to overcome limitations in the information-processing system. The formation of these units can be based on perceptual factors (Bower & Winzenz, 1969), semantic and/or syntactic relationships (Mandler, 1967), or other more elaborate relational organizers, such as interactive imagery (Paivio, 1971). However, there is little if any evidence concerning the differential effectiveness of these relational devices.

One question of primary interest concerns the ease with which units may be encoded and their subsequent stability during output. By employing measures that monitor the temporal flow of information through the processing system, it should be possible to examine the processes involved in unit encoding and subsequent utilization during recall. Recent evidence by Laughery and Schmidt (1970) and Kellas and Butterfield (1971) has indicated that the profiles of study times across input positions manifest distinct patterns that are related to rehearsal activity. These patternings are sensitive to manipulations involving retrieval plans and the formation of higher order memory units (Kellas, Ashcraft, Johnson, & Needham, in press). It was hypothesized in the present study that if *S*s could be induced to use particular relational organizers for the construction of higher order units, the differential ease of unit encoding should be reflected in input exposure times. Using similar logic, the patterning of interresponse times (IRTs) during output should allow an assessment of the extent to which the higher order units served as functional memory units. Patterson, Meltzer, and Mandler (1971), for example, have shown that longer pauses occur at unit boundaries than between items within a unit during recall. Between-group IRTs have been interpreted as representative of a search strategy employed by *S*s to retrieve higher order units. Patterson et al. (1971) postulated that the between-group times are a function of 3 components: (*a*) group exit time, (*b*) group access time, and (*c*) word access time. They suggest that group exit time and word access time remain constant

[1] This investigation was partially supported by U.S. Public Health Service Grants HD-00870 and 00183 from the National Institute of Child Health and Human Development and it formed the basis of a thesis submitted by the first author to the University of Kansas in partial fulfillment of the requirements for the master's degree. Special thanks are due to James F. Juola for helpful comments on earlier drafts of this manuscript.

over successive units recalled, and that increases in between-group times across output positions are due only to changes in group access time. The group access times are in turn assumed to reflect an underlying search process for previously unretrieved units.

In particular, the exponential growth of between-group IRTs across successive output positions has been related to a probabilistic search model (Patterson et al., 1971; Pollio, Richards, & Lucas, 1969) in which *S* is assumed to hold representations of all higher order units in memory. During recall, higher order units are randomly sampled with replacement and subjected to a recognition test to determine if the components of a group have previously been recalled. The exponential growth function actually obtained agrees well with expectations derived from the probabilistic search model. An alternative *fixed*-search model has also been proposed by Pollio et al. Here, it is assumed that *S* stores a fixed sequence of higher order units which are systematically retrieved in serial order during recall. This model also assumes a test phase, in which *S* checks to determine if the retrieved unit has previously been produced. The major difference in predictions between the models involves the latency function describing between-group IRTs across output positions. The probabilistic model would predict an exponential increase, whereas the fixed model is best accommodated by a linear increase in between-group IRTs resulting from the serial component of a fixed search. Existing research does not allow a clear choice of any single model, since Kellas et al. (in press) have recently reported a linear increase in between-group IRTs.

In the present study, an attempt was made to determine whether temporal patterning and search processes comparable to those obtained with categorized materials are involved in the recall of higher order units formed intraexperimentally. To the extent that induced chunking does lead to the formation of functional higher order units, one would expect an interaction of type of IRT (within vs. between group) with output positions, consistent with previous research. The interaction should result from an increase in between-group IRTs across output positions, coupled with little if any increase in within-group times. It should then be possible, by examining the within-group IRTs, to evaluate the cohesiveness of the higher order units, that is, the shorter the latency between responses within a group, the more cohesive the memory unit.

In the present experiment, *S*s were instructed to form higher order units via imagery, sentences, or rote repetition. An uninstructed control group was included to provide a baseline condition against which the effects of induced chunking could be compared. Dependent measures included input and output times as well as response accuracy in order to obtain a more comprehensive view of organizational processes.

Method

Subjects. The *S*s were 60 undergraduate students enrolled in an introductory psychology course who were given class credit for participating in the experiment.

Apparatus. A Sawyer Rotomatic slide projector was used to present the stimuli on a daylight screen. A response button was programmed to the projector so that *S* could control the duration of slide presentation. The latency between the button response and visual presentation was .4 ± .05 sec. The duration of each stimulus presentation was automatically recorded by means of a pulse-stream generator, a parallel-entry control panel, and a Sodeco printout counter. Times were recorded to the nearest .05 sec. The stimuli were typed onto transparency paper and fitted into Easymount 35-mm. frames. A Lafayette Model 810 tape recorder and a lavaliere microphone were used to record *S*s' oral recall. These taped recalls were later channeled into a Mechanics for Electronics Model AHA-20 heat-writing graphic recorder to measure interword response times (IRTs). The *S*s' recall activated a pen that indicated word onset and offset on paper moving at a rate of 25 mm/sec. All IRTs were calculated to include only time between words, and word-production time was excluded from this measure (cf. Pollio et al., 1969).

Lists. The stimulus materials were 144 nouns with high concreteness, meaningfulness, and imaginal values in the Paivio, Yuille, and Madigan (1968) word norms. In addition, all words were rated A or AA in frequency (Thorndike & Lorge, 1944). From this pool, 12 lists of 12 items each were randomly constructed with the restriction that no obvious associations existed within any list. Lists

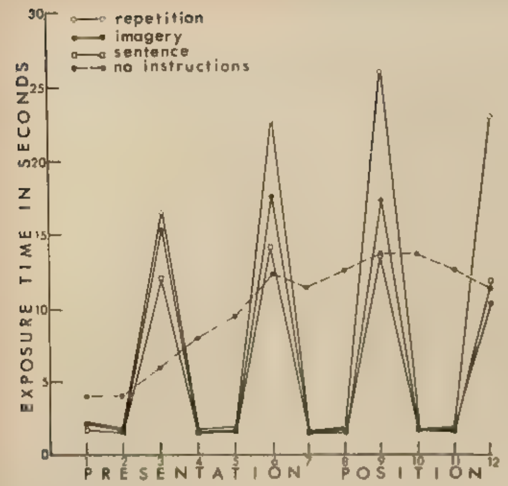

FIG. 1. Mean exposure time for items at each presentation position for all treatment groups.

were equated for concreteness (M = 6.75, SD = .099), meaningfulness (M = 6.94, SD = .146), and imagery value (M = 6.42, SD = .039).

Design and procedure. The *Ss* were randomly assigned to 1 of 4 instruction conditions, yielding a total of 15 *Ss* in each condition. The *Ss* in the no instruction (NI) condition were treated as a control group, and received only standard free-recall instructions. In addition to free-recall instructions, *Ss* in the imagery (I), sentence (S), and repetition (R) conditions were told to learn the lists by grouping items into 3s and forming an interactive image, forming a sentence, or repeating the grouped items contiguously, depending upon their treatment condition. The *Ss* in the I, S, and R conditions were told to expose the first 2 words in each successive group of 3 items only long enough to read them and to then spend as much time as they wished on the third word of each group. All *Ss* were told that item presentation would be self-paced, and that a red field would signal the end of each list and the beginning of the recall period.

The *Ss* were tested individually and received one study and one test trial on each of the 12 lists. The first 2 lists were practice lists and were not included in subsequent analyses. The recall period was unlimited, and *Ss'* oral recall was recorded on magnetic tape for further analysis. Following recall of the final experimental list, all *Ss* were given a 2-page questionnaire. On the first page, they were asked to describe in their own words the method or methods used to learn the items. Page 2 contained a list of possible encoding strategies, including imagery, sentence formation, repetition, and cumulative rehearsal, together with appropriate examples. The *Ss* were to indicate on 9-point rating scales the extent to which they employed each of the suggested strategies.

RESULTS

The major focus of the present research was on the temporal correlates of information processing during storage and retrieval. To the extent that performance approaches error-free responding, time data should provide a relatively pure index of storage and retrieval activities. Analyses pertaining to input processing, recall accuracy, and output processing are presented successively.

Input time. Figure 1 shows the exposure-time profiles across presentation positions for all treatment conditions. Exposure times for the first 2 input positions of each triad are nearly invariant for the instructed conditions, with a mean of about 2 sec. This indicates that *Ss* in these conditions were in fact following the instructions given them to spend only enough time at these positions to read the items. The processing time for each triad, as well as any time spent rehearsing previous triads, is reflected by the sharp peaks at the terminal item of each group.

The mean exposure times for each group of 3 items were computed for all conditions. Whereas these means reflect differences obtained only for the terminal items of each triad for the instructed conditions, they allow comparisons to be made between these groups and the NI condition in which *Ss* were free to spend as much time as they wished at all presentation positions. A 4 × 4 mixed analysis of variance with factors corresponding to instructions (NI, I, S, and R) and presentation position (1–4) was then performed on the mean exposure times for the triads. The main effects of instructions, F (3, 56) = 4.81, $p < .01$, and presentation position, F (3, 168) = 13.26, $p < .01$, were reliable, as was their interaction, F (9, 168) = 3.35, $p < .01$. Mean total input times for each list in the NI, R, I, and S conditions were 121, 104, 75, and 65 sec., respectively. Tukey's (b) multiple comparisons indicated that both the NI and R groups spent significantly more time during input than either I or S groups ($p < .05$). The Instructions × Presentation Position interaction resulted from the relatively large

increase in processing time across positions for the R and NI groups, as compared with relatively constant times in both the I and S conditions. The slight decrease in processing time on the last triad for all groups appeared to be related to *Ss*' tendency to output terminal items first.

Correct responding. A 4 × 10 mixed analysis of variance was conducted on the total correct responses per list in order to examine instruction effects and to ensure that no List × Instruction interaction was present.

The factors corresponded to instructions and experimental lists (1–10). The only significant finding was a lists main effect, F (9, 504) = 5.92, $p < .001$, which resulted from improved recall across lists in all conditions. Mean percent correct responses in the NI, R, S, and I conditions were 84, 80, 76, and 82, respectively.

In previously reported research under *E*-paced conditions, imagery and sentence instructions have typically led to superior performance relative to repetition and uninstructed control groups. It has been suggested (Paivio, 1971) that this recall facilitation may be related to the ease of unit encoding. The results of the present investigation confirm this hypothesis. It is clear that encoding materials in imaginal or sentential form greatly decreased the amount of processing time required by the I and S groups to reach a level of correct responding equal to that of the R and NI groups.

A further analysis of the recall data was conducted to determine the extent to which items grouped during input were recalled contiguously. Since the nominal items which comprise each higher order unit or chunk are known in the instructed conditions, the mean chunk size was computed across output positions for each successive chunk recalled. The NI group was not included, since for this condition the precise nature of the recall units was unknown. Only the first entry into successive chunks for instructed conditions was considered. Reentries into previously accessed chunks were rare and accounted for only 2% of the items recalled. A 3 × 4 mixed analysis of variance was conducted on the chunk-size data, with factors representing instructions (I, S, and R) and output position (1–4). No effect of instructions was obtained, since a high level of clustering according to triad membership occurred for all conditions. (The mean chunk size was 2.34 items across conditions, with a standard deviation of .44.) The analysis yielded only a significant main effect of output position, F (3, 126) = 89.10, $p <$ .001, which resulted from a consistent decrease in chunk size across output positions in all treatment groups. This decrease suggests that the recall of items within a unitized grouping may not be solely dependent upon the accessibility of the higher order unit, but rather is subject to qualifications based on position in output. It is conceivable that interference resulting from output processes may be more detrimental to the individual components within a higher order unit than to the units themselves.

Output time. In order to examine the cohesiveness and search rates for higher order units during output, IRTs were obtained from tape recordings of oral recall. The IRTs from *Ss* in the NI condition were not included as they were not relevant to these issues. Interresponse times involving reentries into previously recalled higher order units and extralist intrusions were excluded from the data and represented only 11.2% of the total responses.

A 3 × 2 × 3 mixed analysis of variance was conducted on the mean IRTs for the instructed groups with factors corresponding to instructions (I, S, and R), type of IRT (within or between chunk), and output position (2–4). Only the last 3 output positions were included in this analysis, since there is no satisfactory way to measure access time to the first word of the first unit recalled. The IRT analysis yielded reliable main effects for instructions, F (2, 39) = 5.67, $p < .001$, type of IRT, F (1, 39) = 91.36, $p < .001$, and output position, F (2, 27) = 22.57, $p < .001$. The highly significant difference for between- and within-chunk IRTs indicates that stable higher order units were established

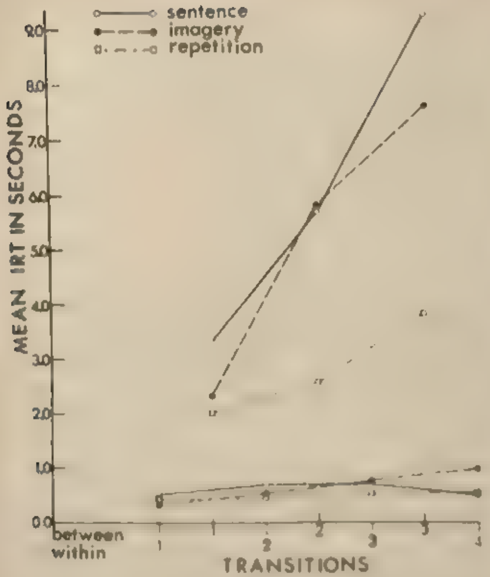

FIG. 2. Mean within- and between-group interword response times (IRTs) as a function of output position for the instructed conditions.

in all instructed groups. The predicted Type of IRT × Output Position interaction was also highly significant, $F(2, 78) = 18.97$, $p < .001$. The between-chunk times can therefore be viewed as representative of the search and retrieval processes for specific higher order units, while the within-chunk times reflect the output of nominal items within higher order units. It is apparent in Figure 2 that the within-chunk IRTs are unaffected by either instructions or output position, suggesting that all higher order units were equally cohesive. The effects of instructions are restricted to the between-group IRTs, as evidenced by the Instructions × Type of IRT interaction, $F(2, 39) = 5.36$, $p < .001$. While the between-chunk times all increased linearly across output positions, instructions had substantial effects on the slopes of these functions and, presumably, the search times for higher order units.

DISCUSSION

The patternings of input and output times strongly indicate that higher order units were formed during encoding by all instructed groups and that these units re[illegible]tional during retrieval. Wherea[illegible] correct responding did not differ am[illegible] ment groups, the input-time data ind[illegible] Ss who organized list materials [illegible] and sentence structures required less [illegible] time to perform the encoding oper[illegible] follows that when Ss are limited [illegible] time constraints, experimental condi[illegible] essarily favor encoding strategie[illegible] image and sentence formation.

One goal of the present research [illegible] to examine the nature of retrieval proce[illegible] higher order units formed intraexperim[illegible] In general, the IRTs observed were con[illegible] with those reported by Pollio et al. (196[illegible] Patterson et al. (1971) with categorized [illegible]ts. However, a major difference is represented by the shape of the between-group functi[illegible] across output positions. Data from the [illegible] which [illegible] paced [illegible] presentation was employed, were described by an exponential function derived from a probabilistic retrieval model. The present results are more consistent with a linear increasi[illegible] [illegible] to that reported by Kel[illegible] et al. (in press). In both the Kellas et [illegible] study and the present investigation, item [illegible]sentation was S-paced, and the high level of correct responding indicated that all u[illegible]ts were highly accessible during the search ph[illegible]se of retrieval. A linear function across output positions could be predicted by at lea[illegible] 2 alternative models of retrieval processes. One is the fixed-search model described, but not empirically supported, by Pollio et al. A linear function could also be predicted by a model based on the trace strength of memory units, as determined by systematic patternings of rehearsal during input (Kellas et al., in press). Rundus (1971) has presented data which indicate that items afforded the most rehearsal during input are typically recalled early in the output sequence. Thus, while the trace-strength model would also assume a fixed retrieval sequence for higher order units, the increase in retrieval times for units at later positions would not result from a reaccess of the memory set at a fixed position, but from an increase in group access times for later units, based on their decreasing trace strengths.

Both linear and exponential functions could be accommodated by a model that includes a parameter related to the accessibility of higher order units. The between-group IRT function would be linear to the extent that units

[illegible] late in the output sequence are ac[illegible] and a consistent retrieval plan remains [illegible]. However, if recall breaks down at [illegible] positions due to inaccessibility of higher [illegible] units, *S* may perform an extended search [illegible] retrieve additional units. This search may [illegible], for example, a repetitive generation [illegible] previously recalled units in an attempt to [illegible] an associative link to unrecalled items, [illegible] by a recognition check for list membership. Consequently, the recall times for [illegible] later units could be expected to increase [illegible]tially.

[illegible] the between-group IRT functions in [illegible] present study are all linear, differences are [illegible] in the slopes of the functions. The [illegible] given repetition instructions were able to [illegible] higher order units significantly faster [illegible] positions than either I or S *Ss*. The [illegible] presented by Patterson et al. (1971) [illegible] that the observed retrieval facilitation [illegible] R condition might best be localized in the group access component. An examination [illegible] suggests an explanation for this facilitation. Little if any increase in processing time [illegible] noted across input triads in either the S or I conditions, while time spent per triad increases nearly linearly in the R condition. This increase provides suggestive evidence that [illegible] rehearsing the earlier presented items [illegible] positions, thereby establishing associa[illegible] among higher order units via cumula[illegible] rehearsal of previously formed triads. This particular encoding process would lead to a decrease in the time required to access additional unrecalled units during recall.

Evidence for the establishment of sequential dependencies in the R condition was obtained from the questionnaires given to all *Ss* following the experimental session. The data from these questionnaires were not previously reported since, for the most part, they simply verify a conclusion drawn from the input-time [illegible] were indeed following instruc[illegible] [illegible] the degree to which *Ss* reported use of cumulative rehearsal in addition to the particular strategy given them, significantly more cumulative rehearsal was reported by *Ss* in [illegible] groups. While such a sequential strategy is [illegible] transitions between units during retrieval.

The high similarity between the IRT data from the present study and research with [illegible] press), suggests a communality in retrieval operations. Pollio et al. (1969) have proposed that retrieval of categorized material is best conceived as a "reconstruction" process, based on the attribute overlap of nominal items to their superordinate label. However, it is difficult to envision such a process operating on higher order units formed intraexperimentally. It seems more parsimonious in both cases to view the retrieval of higher and lower order units as a function of trace strength, determined by the systematic execution of rehearsal processing.

STIMULUS SUFFIX EFFECTS IN DICHOTIC MEMORY

STANLEY R. PARKINSON[2] AND LORA L. HUBBARD

Arizona State University

A very-short-term "preperceptual" or "precategorical" auditory buffer has been proposed by Crowder and Morton as the storage system mediating the retention of items in the terminal serial positions of long lists presented sequentially, and by Broadbent as the storage system mediating retention on the ear reported second or "unattended" ear in dichotic tasks. Previous research has shown that terminal serial position performance in long lists presented monaurally or binaurally is selectively impaired when an extra locution (stimulus suffix) is placed at the end of a list. In the present dichotic memory research, the addition of either a monaural stimulus suffix on the unattended ear or a binaural suffix was shown to selectively impair unattended-ear performance. The comparability of stimulus suffix effects in these tasks suggests that the storage systems mediating retention in dichotic memory are identical with the storage systems operating in the retention of long lists of sequentially presented items.

Crowder and Morton (1969) have recently proposed and extensively investigated (e.g., Morton, Crowder, & Prussin, 1971) a model of auditory–verbal information processing. The major emphasis in their empirical work has been to demonstrate the existence of a very-short-term auditory buffer in which information is thought to reside prior to the process of categorization. The stimuli employed in their research have consisted of long lists of verbal items presented monaurally or binaurally, and the dependent variable has been the retention function measured immediately following stimulus presentation.

Their model is based on the assumption that the primacy and recency effects, obtained in serial position analyses of immediate recall functions, are mediated by two distinct storage systems. They maintain that the first few items presented are categorized and are entered into a short-term or active store while the terminal items are held in an ephemeral (1–2 sec.) precategorical acoustic store (PAS).

[1] This research was supported in part by the U.S. Air Force Human Resources Laboratory, monitored by the Flying Training Division under Contract F41609-72-C-0037. The authors wish to thank Mark Knight and Alan Perey for their assistance in running *S*s in these experiments.

[2] Requests for reprints should be sent to Stanley R. Parkinson, Department of Psychology, Arizona State University, Tempe, Arizona 85281.

The acoustic quality of PAS is inferred from data showing that (*a*) the recency effect in serial position functions is generally greater with auditory than with visual presentation (e.g., Corballis, 1966; Crowder & Morton, 1969); (*b*) recency effects of the magnitude of auditory presentation are obtained with visual presentation if Ss vocalize the stimuli during presentation (e.g., Routh, 1970); (*c*) an additional acoustic element placed at the end of a stimulus list (stimulus suffix) selectively impairs performance over the terminal serial positions (Crowder & Morton, 1969; Morton et al., 1971); and (*d*) the stimulus suffix is effective only if both stimulus list and suffix are presented aurally (Morton & Holloway, 1970).

The precategorical nature of PAS is inferred from findings indicating that the magnitude of the stimulus suffix effect is unaffected by either the frequency of occurrence or emotionality of words employed in the suffix position, or the semantic similarity between stimulus list and suffix (Morton et al., 1971).

The model and theoretical constructs proposed by Crowder and Morton (1969) are very similar to those of Broadbent (1971). Working with a dichotic paradigm, Broadbent found that when *S*s were given 2 lists of digits simultaneously, one to each ear, they were more accurate if they first recalled the items from one ear and then

the items from the other (ear-by-ear report) than if they reported items by pair (pair-by-pair report) according to their order of arrival. Broadbent took this finding to imply the existence of a stage of parallel processing (S or storage system) followed by a stage of sequential processing (P or perceptual system). According to the model, both messages of a dichotic pair enter the S system in parallel. A selective filter, operating in time between the S and P systems, selects one message for entry into the P system and attenuates processing of the other message. The P system processes the items in the selected message and that message is reported first during recall. The initially unselected message is held in the S system and that message does not gain access to the perceptual system until the completion of first-ear processing. Like PAS, the level of information processing in the S system is preperceptual or precategorical.

Comparison of the Broadbent (1971) and Crowder and Morton (1969) models reveals that both distinguish between storage systems in which information is relatively unanalyzed, preperceptual or precategorical (S system and PAS, respectively), and storage systems in which information is processed or categorized (P system and short-term or active store). Although the theoretical constructs S system and PAS are derived from different experimental paradigms and hence remain operationally distinct, much theoretical power could be gained by establishing a "working equivalence" between them.

If the storage systems mediating retention in dichotic tasks are the same as those mediating retention with a single auditory channel, we should be able to accurately predict dichotic performance given the single-channel performance. Parkinson (1974) assessed conventional single-channel digit spans and grouped *S*s according to that measure in a dichotic memory task. He found a correlation of +.891 between digit span and overall dichotic performance. This relationship lends considerable support to the merit of establishing a working equivalence between constructs derived from the dichotic task and those derived from a task in which long lists of items are presented over a single auditory channel.

Another way of evaluating a working equivalence between constructs would be to show an effect of an independent variable in one task that is known to be effective in the other task. Precategorical acoustic storage is thought to mediate retention of items occurring in the terminal serial positions of long lists presented monaurally or binaurally. Crowder and Morton (1969) and Morton et al. (1971) have shown that retention of terminal serial position items is selectively impaired by an extra acoustic locution (e.g., "uh") placed at the end of a stimulus list (stimulus suffix). The S system of Broadbent (1971) is thought to mediate the retention of the "unattended" ear or the ear reported second in dichotic tasks. If the S system were equivalent to PAS, a stimulus suffix placed at the end of a dichotic list should selectively impair unattended-ear performance. It is the purpose of the present experiments to explore stimulus suffix effects in dichotic memory.

Experiment I

Method

Subjects and design. Sixteen introductory psychology students served as *S*s in the present experiment. The *S*s were tested individually in a sound reduction chamber and they were paid for their participation. Morton et al. (1971) found that the magnitude of the stimulus suffix effect varied as a function of the similarity of "apparent spatial location" between suffix and stimulus list. Therefore, suffix location was manipulated in the present experiment as a between-*S*s factor. Individual single-channel digit spans were assessed prior to the experimental sessions (Parkinson, 1974), and each *S* was then assigned to one of 4 groups that determined the location of the stimulus suffix to be received: control—no suffix; monaural suffix—attended ear; monaural suffix—unattended ear; and binaural suffix. The method for assigning *S*s to groups roughly equated all 4 groups for mean digit span.

Materials and apparatus. On each trial *S*s received 2 lists of digits simultaneously, one to each ear. All lists were recorded by the same male speaker at the rate of 2 pairs per second. Stimulus lists were recorded on a TEAC model TCA-42 4-channel tape deck and they were played to *S*s via stereo headphones (Superex Pro-BV). The stimulus lists were constructed from the set of

numbers 0–10 and no number appeared twice on a given trial.

The stimuli were recorded on 5 audiotapes, one practice and 4 test. The practice tape was comprised of 42 dichotic lists, each list consisting of 4 digits per ear (8 digits per trial). The 4 test tapes each contained 72 dichotic lists with 5 digits per ear (10 digits per trial). One of these test tapes was used in the first experimental session to establish baseline performance for all 16 *S*s in the dichotic task. In the remaining 3 test tapes a stimulus suffix was placed at the end of each stimulus list. A monaural stimulus suffix was placed at the end of each list in 2 of these tapes, on the right channel for Tape 3 and on the left channel for Tape 4. On Tape 5, a binaural suffix was placed at the end of each stimulus list. In all cases (whether monaural or binaural) the stimulus suffix was the locution "uh." The suffix was recorded in the same voice and in the same tempo as the digit list.

Procedure. According to the Broadbent (1971) model, *S*s attend to one ear during stimulus presentation and report that ear first during recall. In previous research (Bryden, 1971; Parkinson, 1974), the ear of attention has been controlled by instructing each *S* to "attend" to a particular ear during the course of an experiment. A payoff schedule was introduced in the present experiments to meet the same purpose. Each *S* was told that he would receive 1 cent for each digit recalled in the correct order for one ear, hereafter referred to as attended ear, and ½ cent for each digit on the other ear, hereafter called unattended ear. The ear receiving maximum payment was balanced within each group (2 left ear and 2 right ear) and, for each *S*, remained constant during the course of the experiment. The *S*s were told to earn as much money as they could, and feedback regarding the amount earned was given following *S*'s response on each trial.

The *S*s were instructed to report ear by ear. Following a procedure developed by Bryden (1971), order of report was manipulated, i.e., on one half of the trials *S*s were instructed to report attended ear first and unattended ear second (A–U report), and on the other half of the trials unattended ear first and attended ear second (U–A report). Unlike the Bryden procedure, in which order of report was blocked, report instructions were delayed until the end of each stimulus list and the order of report was randomized. The ear to be recalled first (left or right; for *S*, attended or unattended) was indicated by the onset of one of 2 lights at the end of each stimulus list. The lights, one red and one green, were oriented horizontally on a panel in front of *S*s to coincide with right and left ears. Tone bursts recorded on a third channel of the tape triggered the lights to come on immediately following list presentation. In the suffix conditions, the indicator light was presented immediately following the suffix. It was thought that the delayed order-of-report instructions coupled with the payoff schedule would encourage *S*s to differentially process attended- and unattended-ear messages.

At no time were *S*s required to recall all 10 items. The *S*s were instructed to report only those items they actually remembered from the unattended ear. In order to receive maximum payment for his report on each trial, *S* had to follow order-of-report instructions as indicated by the lights, i.e., report digits in correct serial order for each [illegible] The *S*s' verbal responses were written down by E and compared with mimeographed copies of [illegible] dichotic lists actually recorded on each of the [illegible] Following *S*'s report on each trial, *E* assessed errors made by *S* and told him how much he earned for that trial. Although serial recall scoring was used in determining payment, free recall scoring was used in data analysis.

The *S*s from all 3 suffix groups were told before the second test session that an extra locution ("uh") would occur following each list, and they were informed which ear would be receiving the suffix. They were told to continue to do what they had been doing in the previous session, to ignore the suffix, and not to report it during recall. In the second test session the control group repeated the session with the first test tape with headphones reversed so that attended and unattended messages were reversed.

Results

Raw scores were converted to percentage correct recall and separate 2 × 3 (Between × Within) analyses of variance (ANOVAs) were conducted on data obtained in the first and second test sessions. Between-groups factors in these analyses were ear of attention and suffix group. Within-groups factors were order of report (A–U vs. U–A), attention (A vs. U), and serial position. Baseline and suffix performance is shown in Figures 1–4 for the control group, attended-ear suffix group, unattended-ear suffix group, and binaural suffix group, respectively. As there was no interaction between order of report and type of suffix, performance in both sessions is shown collapsed over order of report.

Baseline test. Comparison of the baseline performance shown in Figures 1–4 indicates that prior to experimental treatment (administration of a stimulus suffix) the 4 groups were not different. This was confirmed in statistical analysis, as neither the main suffix group factor nor any of the suffix group interaction factors were reliable, all $ps > .05$.

As in previous research in which order of report was manipulated (Bryden, 1971;

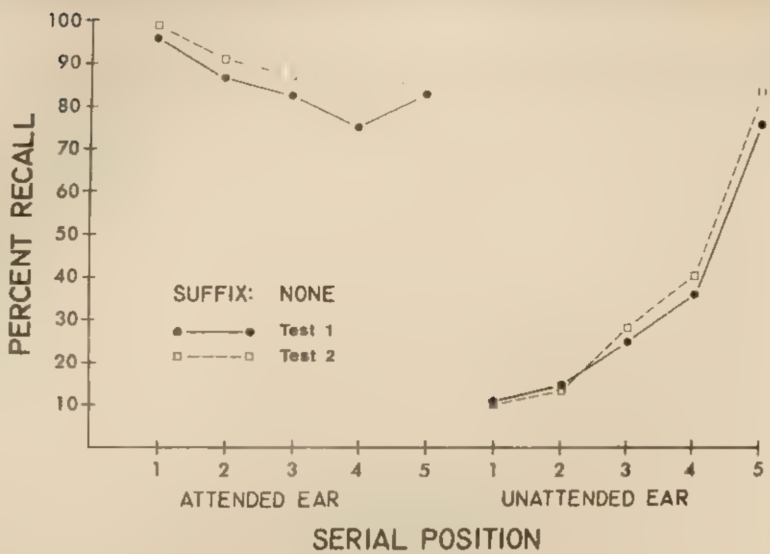

FIGURE 1. Control group, Experiment I: Percentage recall in the first and second test sessions as a function of ear of attention and serial position.

Parkinson, 1974), performance on the attended ear was superior to performance on the unattended ear, $F\ (1, 8) = 191.31$, $p < .001$, and A–U reports were superior to U–A reports, $F\ (1, 8) = 17.64$, $p < .003$. Serial position functions for the attended ear were relatively flat while positively increasing serial position functions were obtained for the unattended ear, $F\ (4, 32) = 101.52$, $p < .001$.

Suffix test. Based on the Broadbent (1971) model and on the findings of Morton et al. (1971), we would predict that stimulus suffix effects would be limited to the terminal serial positions of the unattended ear in conditions in which the un-

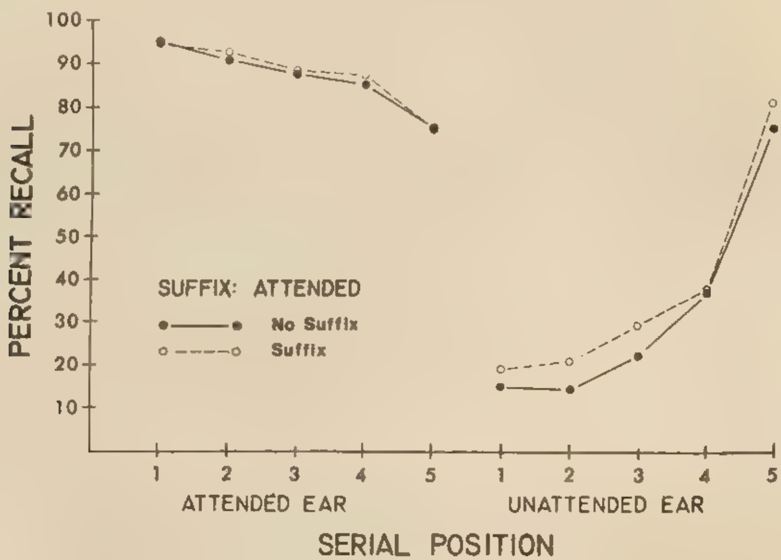

FIGURE 2. Attended-ear suffix group, Experiment I: Percentage correct recall as a function of test (suffix vs. no suffix), ear of attention, and serial position.

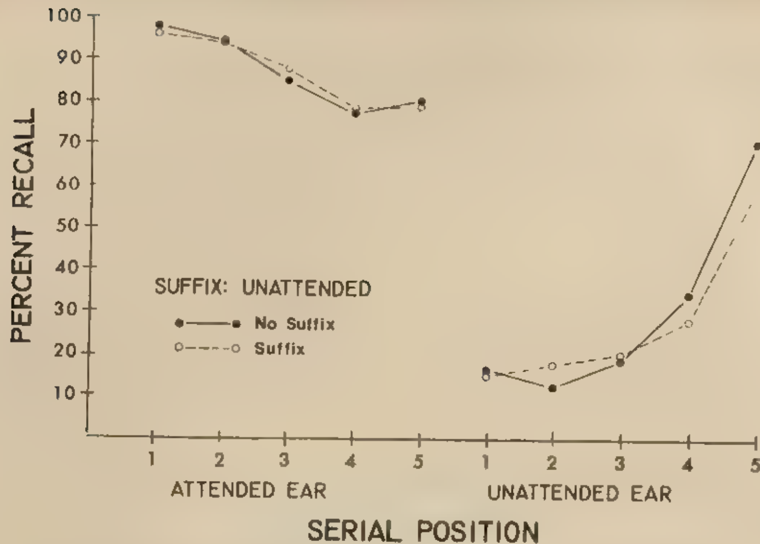

FIGURE 3. Unattended-ear suffix group, Experiment I: Percentage correct recall as a function of test (suffix vs. no suffix), ear of attention, and serial position.

attended ear received input subsequent to the stimulus list. In the present experiment this occurred in only the unattended suffix and binaural suffix groups. No effect should be observed in the attended suffix group.

Inspection of Figures 1–4 reveals that stimulus suffix effects were indeed limited to the terminal serial position of the un attended ear in the unattended suffix an binaural suffix groups. Results of t ANOVA indicated a reliable Suffix Gro × Serial Position interaction, F (12, 32 2.41, $p < .02$, and a Suffix Group × tention × Serial Position interaction. (12, 32) = 2.64, $p < .01$. Neither the

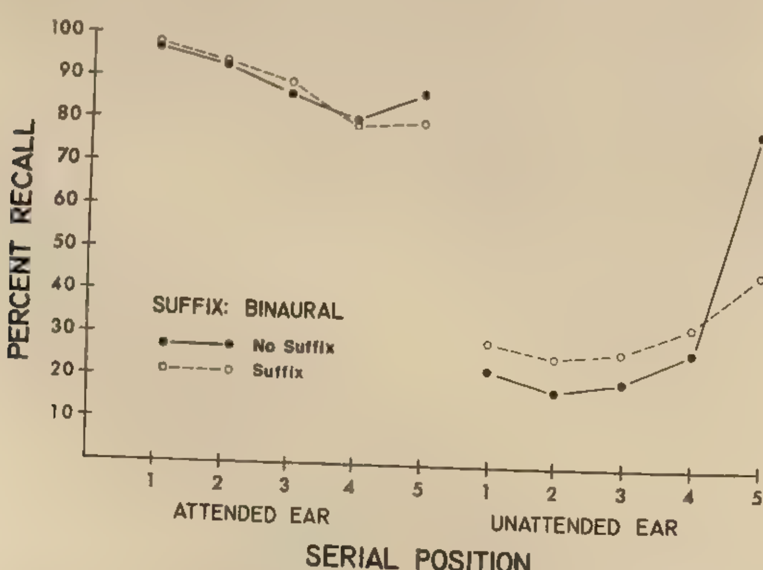

FIGURE 4. Binaural suffix group, Experiment I: Percentage correct recall as a function of test (suffix vs. no suffix), ear of attention, and serial position.

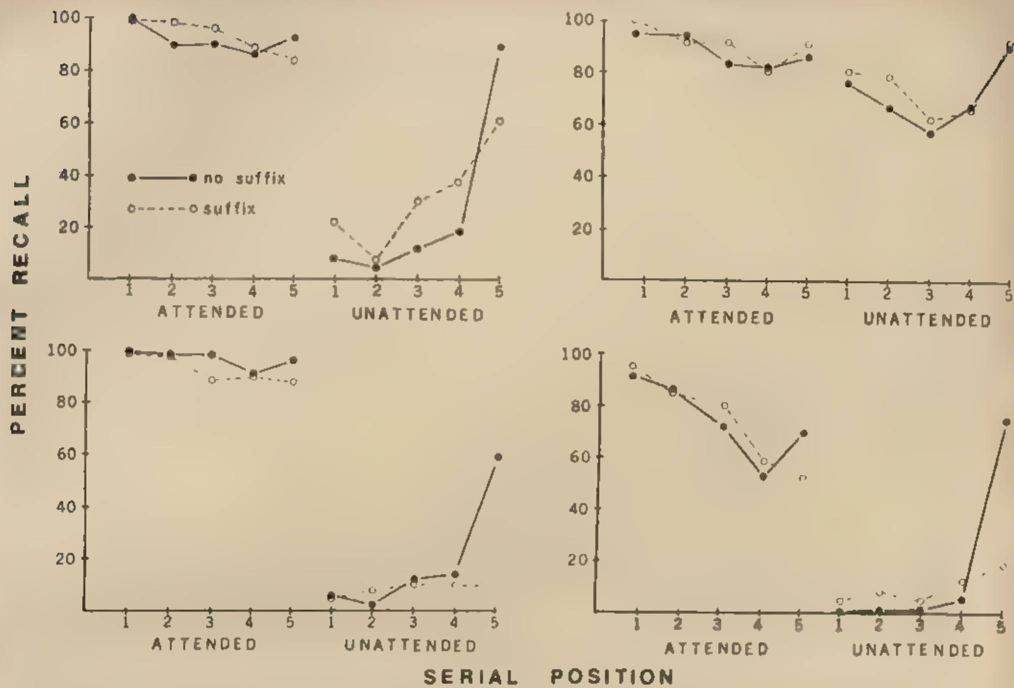

FIGURE 5. Individual data ($N=4$), binaural suffix group, Experiment I: Percentage correct recall as a function of test (suffix vs. no suffix), ear of attention, and serial position.

main effect of suffix group nor any of the other suffix group interactions were reliable.

Difference scores between baseline and suffix conditions were obtained for all *Ss* on the terminal serial position of the unattended ear. As a test of the reliability of the suffix effects, *t* tests were conducted on the difference scores. The *t* tests showed reliable decrements in the unattended suffix group, $t\ (6) = 3.15$, $p < .02$, and the binaural suffix group, $t\ (6) = 3.44$, $p < .02$, relative to the control group, but no difference between the control and the attended suffix groups, $t\ (6) < 1$.

The comparability of suffix effects in the present experiment with those in the Morton et al. (1971) study suggests that the storage systems mediating retention in dichotic memory are identical with the storage systems operating in the retention of long lists of sequentially presented items.

The binaural suffix group had the largest stimulus suffix effect (mean decrement on the terminal serial position = 33.25%); however, there was considerable variability between *Ss* in this group with regard to the magnitude of the suffix effect. Considering only the terminal serial position, the suffix effects of the 4 *Ss* in the binaural suffix group were 55%, 50%, 28%, and 0 (see Figure 5). Of considerable interest is the fact that there was an orderly relation between magnitude of suffix effect and digit span. The *Ss* showing the largest suffix effects had digit spans of 5 and 7, the *S* with an intermediate suffix effect had a digit span of 9, and the *S* with no demonstrable suffix effect had a digit span of 11. Experiment II was conducted in order to further delineate the relation between magnitude of suffix effect and digit span.

EXPERIMENT II

Method

Digit spans were assessed and only individuals with a high or low digit span were selected for participation as *Ss*. Sixteen *Ss* were assigned on

the basis of digit span to one of 2 groups: high span or low span. The Ss in the high-span group had individual digit spans of 10, 10, 9, 10, 9, 10, 10, and 10, with a mean of 9.75. Ss in the low-span group had individual spans of 6, 7, 7, 6, 6, 6, 6, and 6, with a mean of 6.25. The Ss received the same test sequence (one practice session followed by 2 test sessions) and same instructions as those employed in the first experiment. One half of the Ss in each group received maximum payment for right-ear performance and one half for left-ear performance.

In the present experiment, the stimulus suffix ("uh") was presented binaurally for both groups.

Results

As the primary concern in Experiment II was the relation between digit span and stimulus suffix effect magnitude, the data were collapsed over order of report and separate 2 × 2 (Between × Within) ANOVAs were conducted for attended-ear reports and for unattended-ear reports. In these ANOVAs, span and ear of attention were between-groups factors while test (baseline vs. suffix) and serial position were within-groups factors. The results for the low-span group and for the [illegible]

low-span group to be a positively increas[illegible] function of serial position. The [illegible] responding function of the high-span gr[illegible] (Figure 7) shows level of accuracy to [illegible] relatively flat over the first 4 serial [illegible] tions, with somewhat higher perform[illegible] on the terminal item. Statistical ana[illegible] revealed significant main effects of [illegible] F (1, 12) = 157.25, $p < .001$, and serial position, F (4, 48) = 22.84, $p < .001$, and a reliable Span × Serial Position interaction, F (4, 48) = 3.01, $p < .03$. These findings provide confirmation of earlier results (Parkinson, 1974) showing an [illegible] relation between unattended-ear rec[illegible] curacy and digit span.

Inspection of Figures 6 and 7 shows [illegible] the effect of a binaural stimulus suffix [illegible] limited to the terminal serial position, and statistical analysis revealed the Test (b[illegible] line vs. suffix) × Serial Position int[illegible] action to be reliable, F (4, 48) = 2[illegible] $p < .001$. This result replicates [illegible] obtained with the binaural suffix group [illegible] Experiment I and provides a clear dem[illegible] stration of a stimulus suffix effect in dicho[illegible] memory. Of further interest is the mag[illegible] tude of the stimulus suffix effect. The mean decrement in the terminal serial position (baseline suffix) for the low-span group

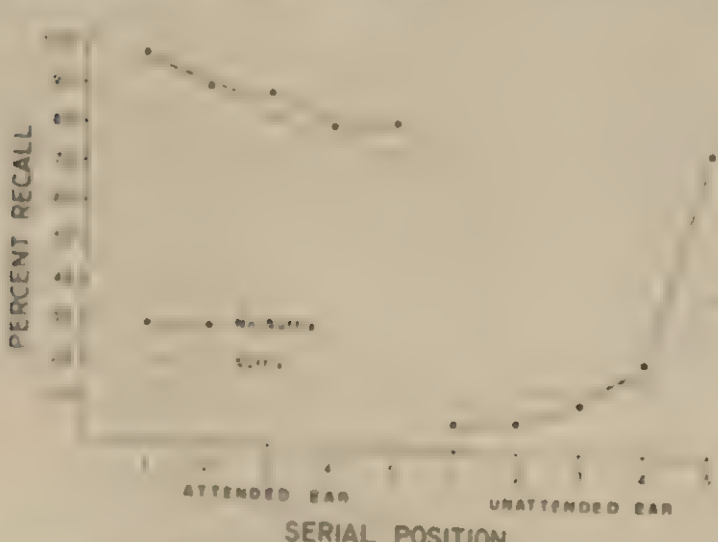

FIGURE 6. Low-span group, Experiment II. Percentage correct recall as [illegible]

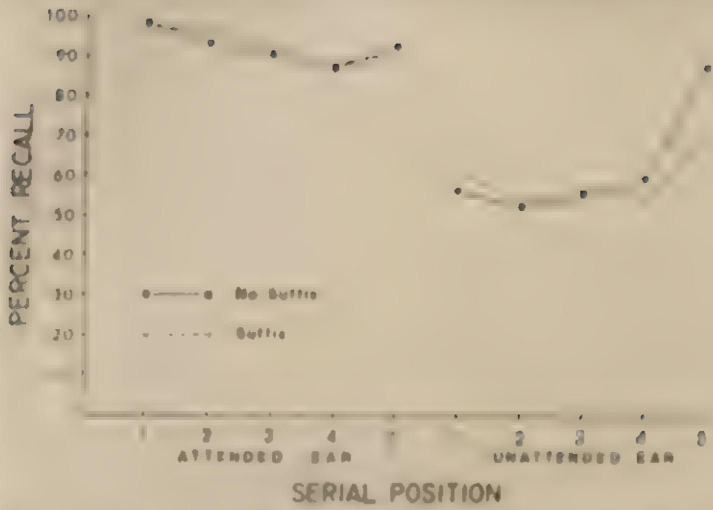

FIGURE 2. High span group, Experiment II. Percentage correct recall as a function of test (suffix vs. no suffix), ear of attention, and serial position.

[illegible]%, while that for the high span [illegible] 16.04%. The Span × Test × Serial Position interaction was reliable, F (4, 48) = 3.01, $p < .05$.

[illegible] ear recall. The effect of span [illegible] limited to the unattended ear [illegible] span group also performed more [illegible] than the low span group on the [illegible], F (1, 12) = 12.16, $p < .005$, with the greatest disparity between groups on the terminal serial positions, F (4, 48) = [illegible], $p <$ [illegible].

[illegible] was also an effect of the stimulus [illegible] on the attended ear, as indicated by [illegible] × Serial Position interaction, F [illegible] control to the low span group, F (1, 12) = [illegible], $p < .05$. The third-order interaction between span, test, and serial position was not reliable.

Discussion

[illegible] group of Experiment I is now clear, [illegible] stimulus suffix effects [illegible]

[illegible] span [illegible] the nature of the difference between [illegible] high and low digit span which results in different magnitudes of the stimulus suffix effect? The most obvious possibility is that the magnitude of the stimulus suffix [illegible] the amount of stimulus [illegible]

[illegible]

[illegible] unattended ear [illegible] digit correctly recalled [illegible]

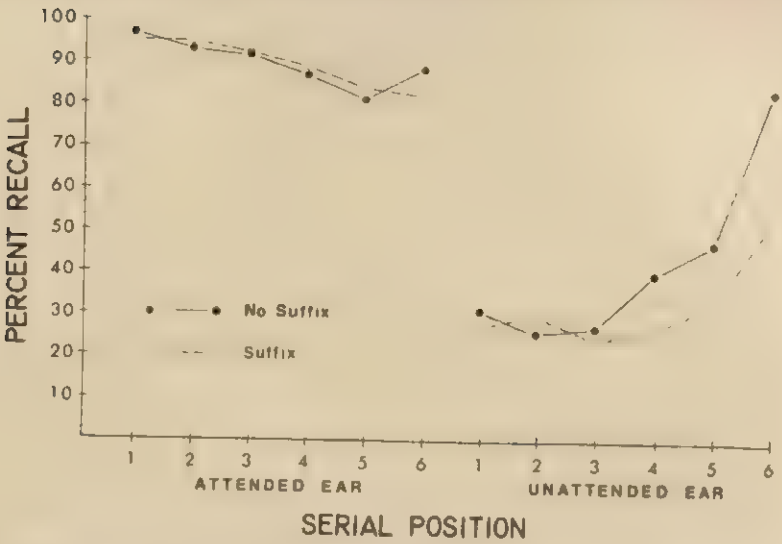

FIGURE 8. Group data, Experiment III: Percentage correct recall as a function of test (suffix vs. no suffix), ear of attention, and serial position.

Results

As in Experiment II, the data were collapsed over order of report and separate ANOVAs were conducted on attended-ear and unattended-ear performance. These results are shown in Figure 8.

Attended-ear recall. The only effect reliable in attended-ear analyses was the main effect of serial position, with primary serial positions better recalled than terminal serial positions, $F(5, 30) = 8.81$, $p < .001$.

Unattended-ear recall. Baseline performance was superior to that observed when a stimulus suffix was administered, $F(1, 6) = 10.01$, $p < .02$, and terminal serial positions were recalled with greater accuracy than primary serial positions, $F(5, 30) = 13.49$, $p < .001$. Inspection of Figure 8 reveals the stimulus suffix effect to be restricted to the terminal serial positions, and statistical analysis showed the Test $\times$ Serial Position interaction to be reliable, $F(5, 30) = 4.90$, $p < .002$.

Of considerable interest is the resemblance of the unattended-ear serial position function for the high-span *S*s in the present experiment (with dichotic lists containing 6 digits per ear) to the unattended-ear serial position function of the low-span *S*s in Experiment II (with dichotic lists containing 5 digits per ear). Both of these show unattended-ear accuracy to be a positively increasing function of serial position. There is also considerable similarity in terms of the magnitude of the stimulus suffix effect in these functions. The mean decrement on the terminal serial position (baseline-suffix) was 28.75% in the present experiment. This can be compared with the 29.16% and 16.04% decrements shown by the low-span and high-span groups, respectively, in Experiment II. A difference score (baseline–suffix) was computed for the terminal serial position performance of high-span *S*s in Experiment II and Experiment III. A correlated *t* test of these differences indicated a reliably larger decrement in Experiment III, $t(7) = 2.51$, $p < .05$.

GENERAL DISCUSSION

According to the Broadbent (1971) model, attention is directed to one message in the dichotic task. That message enters the P or perceptual system while the initially unattended message is held in a short-term auditory buffer, the S system. In this model information is held in different storage systems and these systems can be characterized by different levels of processing. Information held in the S system is relatively unanalyzed while information in the P system is cate-

gorized. Given this type of model we would expect (*a*) differences in the recall functions of attended and unattended messages, and (*b*) differential effects on attended and unattended messages from an independent variable (stimulus suffix) which is thought to selectively interfere with relatively unanalyzed information. Both of these expectations were realized in the present experiments.

Another finding of considerable interest in the present experiments was that the magnitude of the suffix effect was directly proportional to the amount of stimulus overload, i.e., the degree of disparity between an individual's digit span and the number of to-be-remembered items. In Experiment II, given messages containing 5 digits per ear, *S*s with low digit spans showed larger stimulus suffix effects than did *S*s with high digit spans. That it was the disparity between digit span and number of items, and not digit span per se, which was important, was revealed in Experiment III, in which *S*s with high digit spans showed larger stimulus suffix effects when they were given dichotic lists containing 6 digits per ear.

How can we interpret the relationship between digit span and suffix effect? First consider results obtained by Parkinson (1974). He manipulated order of report in dichotic memory and found correlations of +.881 and +.844 between digit span and unattended-ear performance in attended–unattended and unattended–attended reports, respectively. Parkinson offered two interpretations of his results one based on S system storage capacity and one based on "central processing capacity." Attempts to delineate the relationship between digit span and suffix effect magnitude will be oriented along these interpretations.

Storage Capacity

One interpretation of the relation between digit span and unattended-ear performance is that S system capacity varies as a function of digit span. Accordingly, *S*s with high digit spans have more "storage bins" in their S system than do *S*s with lower digit spans. The stimulus suffix in the present experiments was presented in the same voice and tempo as the stimulus list; hence, the relation was one of high similarity. Morton et al. (1971) manipulated similarity between stimulus list and suffix along dimensions of intensity, pitch, and apparent spatial location. They found the magnitude of the stimulus suffix effect to be directly proportional to the degree of similarity between suffix and stimulus list. Reports of *S*s in the present experiments indicated that the degree of similarity between the suffix and the stimulus list made it very difficult for them to ignore the suffix during presentation. One way of viewing this effect is that as the similarity between stimulus list and suffix increases, *S*s find it more difficult to separate out or isolate the suffix from the stimulus list and the suffix comes to "act" like an additional item in the list. Given a system of storage bins and a displacement principle, the suffix would simply displace the last item in the list as the last stimulus item displaces the penultimate item. Given sufficient storage bins (higher-span *S*s), the displacement would not affect recall to any great extent; but given more items than bins (low-span *S*s in Experiment II and high-span *S*s with more items as in Experiment III), the effect of a suffix would be to even further overload the system and the result would be a significant impairment of recall performance.

Central Processing Capacity

In some models of information processing, attention is used synonymously with central processing capacity (CPC) or "mental effort" (e.g., Kahneman, 1973; Posner & Boies, 1971). Models of this type posit a finite amount of CPC that is available for information processing. Mental operations requiring CPC share a common source; thus, if a large amount of CPC is invested in one operation, the amount remaining for others is reduced.

Consider that the present task consists of 2 components, recall and separation or isolation of the suffix from the stimulus list, both of which require CPC. The effects on recall observed following manipulation of similarity between stimulus list and suffix (Morton et al., 1971) can be viewed in terms of the amount of CPC required by the isolation component. In the high-similarity conditions, more CPC was required by the isolation process than in the low-similarity conditions; therefore the amount remaining for recall was insufficient to maintain accurate performance.

In Experiment II of the present research, both groups, high and low span, were given binaural suffix presentation in the same voice and tempo as the stimulus list. We can assume from the findings of Morton et al. (1971) that some amount of CPC was demanded in the present experiment to separate

the stimulus list and suffix. Parkinson (1974) hypothesized that the CPC required for recall varied in direct proportion to the difference between an individual's digit span and the number of to-be-remembered items. Assuming Parkinson's hypothesis to be correct, more CPC was demanded in the recall task of Experiment II for the low-span group than for the high-span group. Given a condition in which substantial CPC is needed for recall, any CPC diverted to the separation of stimulus list and suffix should be sufficient to impair recall performance. We would expect on this basis a greater discrepancy between baseline and suffix test performance for the low-span group than for the high-span group. We would also expect that as CPC requirements for recall were increased for the high-span group by increasing the number of items (Experiment III) a greater difference would exist between baseline and suffix performance. Both of these results were obtained in the present experiments.

The purpose of the present experiments was to evaluate the merit of establishing a working equivalence between theoretical constructs derived from dichotic memory and from procedures in which long lists of items are presented sequentially. The comparability of stimulus suffix effects in the present experiments to those of Morton et al. (1971) suggests that the storage systems mediating retention in dichotic memory are identical with the storage systems operating in the retention of sequentially presented items

RETROACTIVE INHIBITION OF RHYME CATEGORIES IN FREE RECALL:

INACCESSIBILITY AND UNAVAILABILITY OF INFORMATION[1]

DOUGLAS L. NELSON[2] AND DAVID H. BROOKS

University of South Florida

This experiment was designed to investigate retroactive inhibition in free recall of categorized word lists with categories defined as sets of rhymes. Each *S* learned 1–6 lists prior to being tested for total free recall of all words from all lists. Following this test, half of the *S*s were given a second total free-recall test and half of the *S*s were given a cued-recall test. The cues consisted of sequences of letters which, when pronounced, rhymed with 4 of the words from the list. The results indicated that retroaction effects were evident for the recall of words, categories, and for words within recalled categories. Providing retrieval cues eliminated retroaction effects but, simultaneously, depressed the number of words recalled per category. An analysis of extralist intrusions suggested that the loss of instances within recalled categories arose because of the difficulty of discriminating between intralist and extralist instances.

Tulving and Psotka (1971) have shown that retroactive inhibition in the free recall of categorized word lists is apparently produced by the loss of higher order memory units rather than instances falling within those units. Furthermore, since providing category names as retrieval cues essentially eliminated retroaction, they concluded that this loss reflected the inaccessibility rather than the unavailability of the higher order units. These findings were interpreted as indicating that words of a conceptual category are "stored together" as a functional unit. Providing the name for an apparently forgotten memory unit ostensibly provided retrieval access to most of the instances coded within it.

This experiment was concerned with whether or not rhyme categories could serve as functional units of memory and with determining if rhymes could serve as effective retrieval cues for recalling instances coded within these categories. To implement these aims, the basic procedures of the Tulving and Psotka (1971) study were replicated using rhyme-defined categories. Findings were expected to be relevant to recent conceptualizations of word-coding processes. Despite the growing consensus that words are represented in memory as sets of features, attributes, or dimensions (e.g., Gibson, 1971; Underwood, 1969; Wickens, 1970), very little research on organizational processes in free recall on other than semantic attributes has been reported. Thus, one aim of this experiment was to show that the forgetting of rhyme categories could be described as an analogue of the forgetting of conceptual categories, or alternatively, to show that memory processes involved in phonetic representation are different from those involved in semantic representation.

The experiment was designed to provide evidence on 2 specific questions. First, does the acquisition of other lists reduce the recall of higher order units, instances within those units, or both? If rhymes are organized into functional units during the study phase of the task, i.e., if they are in some sense stored together in a manner analogous to conceptual categories, then retrieval of the rhyme category ought to mediate the recall of most of its instances. If this supposition is correct, retroaction ought to be reflected in the

recall of categories, not in the recall of instances within categories. However, there are inherent differences between the 2 types of categories, differences which may affect the manner of the processing of instances. If rhyme categories are not represented in memory as units, then retroaction may be apparent only within the number of words recalled from each list. Alternatively, rhyme categories may be represented in memory as subjectively organized units, but because of their unique qualities, recalling the unit or category may be insufficient for mediating recall of its instances. If so, then retroaction effects would be reflected in category recall and in the recall of words within recalled categories.

The second question of interest concerned the status of information loss produced by the learning of other structured lists. Does retroactive inhibition reflect the unavailability of information, its inaccessibility, or both? Evidence relating to this question will be provided by presentation of rhyme categories as retrieval cues following free recall. If retroaction is produced by a loss of information from storage within the context of the task, rhyme cues should be ineffective as retrieval aids. If retroaction is produced only by the inaccessibility of information, these retrieval cues might provide access to the information so that forgotten items might be recovered. Of course, it is possible that these cues may be differentially effective at the levels of "units" and "instances." Providing rhymes as retrieval cues may provide access to forgotten categories, but these categories, in turn, may be insufficient for generating most of the list words occurring within these categories. In this case, retroaction would reflect the inaccessibility of higher order units and the unavailability of instances within those units.

Method

Design. There were 8 independent groups of *S*s differing in terms of number of lists learned, and whether second total recall of all words from all lists was either free or cued. Thus, *S*s learned 1, 3, or 6 different lists; following the first total free-recall test, half of the *S*s were given a second total free-recall test and half were given a [c]ued-recall test. Controls acquired a single list, [fol]lowing a delay appropriate for the first list lear[ned] in the 6 list condi ions and following the first [tota]l free recall, half of the controls were given [a] second total free-recall test and half were give[n a] cued-recall test. The controls will be referred [to] as 1D, i.e., a one-list delay condition. Thus, t[he] experimental design conformed to a 4 × 2 × [2] mixed-model factorial, the between-*S*s facto[rs] being number of lists learned (1D, 1, 3, or 6) [and] type of recall (free or cued), and the within[-*S*s] factor being order of recall (first total recall [vs.] second total recall). Since the first total reca[ll] was always free, comparisons of type of re[call] at this point provide information only on the [com]parability of the free and cued groups. Therefore, given this design, meaningful comparisons will b[e] reflected only in interactions between type of r[ecall] and order of recall. That is, for a given m[easure] of performance the effects of cued recall [wou]ld be apparent on the second test and not on [th]e first test. Type of recall was made a betwee[n-*S*s] variable because of the significant improv[eme]nt in performance from the first "total" free-[reca]ll test to the second "total" free-recall test o[bta]ined by Tulving and Psotka (1971). To the [exten]t that performance improves with successive recall tests, some of the improvement obtained in [cued] recall might have been reasonably attributed [t]o this factor. However, because cued recall was [prec]eded by free recall, it was also possible with this design to evaluate the effects of cuing as a [wit]hin-*S*s variable.

Verbal material. Six different 24-word lists were constructed with each list containing 6 categories of 4 words. Items within each category, all relatively common words, consisted of monosyllabic rhymes taken from Wood's (1971) unabridged *New World Rhyming Dictionary*. Thus, with 6 lists and 6 categories/list, there was a total of 36 different rhyme categories. Within a given category of 4 words, all items were both phonetically and visually similar, sharing 2–4 letters in the terminal positions. According to a tabulation and count of words selected from Wood's dictionary there was an average of 15.00 (SD = 4.88) words sharing each ending for each of the 36 categories used in this experiment. The smallest set contained 8 items and the largest contained 24 items. All first letters within a given rhyme category were different and were consonants. In addition to these constraints, no homophones were used in any of the lists, and an attempt was made to minimize obvious associative relationships among items in all lists. Furthermore, an attempt was made to maximize the number of unique word beginnings. There was a total of 42 different beginnings for the 144 words, counting B . . . as different from BR . . . .

In each list all words of a given rhyme category were presented in immediate succession, in a "block," e.g., DITCH, WITCH, STITCH, PITCH, BOOT, LOOT, ROOT, SHOOT, etc. Latin squares were used

to counterbalance the order of appearance of the categories within a given list as well as the ordinal position of lists for groups acquiring more than a single list. The order of the items within a given rhyme category was unsystematically randomized for each *S*.

Procedure. All *S*s participated in individual sessions. In immediate recall, the words were shown, one at a time, by a Kodak Carousel slide projector driven by an auxiliary timer so that each word was shown for 1 sec. Every list was shown 3 times in succession, each time in a different order, before its recall was tested. There was a 10-sec. interval separating successive inputs. Following the third presentation, *S*s were allowed 90 sec. to write down as many words as could be recalled in any order. Guessing was encouraged but not required. The recall sheet contained 24 unnumbered, horizontal lines arranged into 6 groups of 4 lines. Upon completion of the recall phase *S* handed his protocol to *E* who provided a new sheet if there was another list. The next list was presented as soon as the recall sheets were exchanged.

The immediate recall test of the last list was followed by 5 min. of interpolated activity consisting of solving multiplication and long division problems. Speed and accuracy were emphasized. Since the 6-list condition required 25 min. for the immediate recall series, *S*s in the 1D condition engaged in this task for 30 min. so that this interval was equivalent to 5 lists plus 5 min. of interpolation.

Following the interpolated task, all *S*s were given a total free-recall test. Each *S* was provided with new recall sheets and was instructed to write down as many words from all previous lists as he could, in any order. Recall time was equal to 90 sec. multiplied by the number of lists. After the protocols were collected, half of the *S*s in each condition were asked to provide a second total free recall and the other half of the *S*s in each condition were given instructions for cued recall. The latter indicated that all words from all lists were to be recalled but that cues would be provided on the recall sheets to aid them. They were informed that these cues would consist of groups of letters which, when pronounced, would rhyme with 4 of the words presented, e.g., "$\overline{\text{OOT}}$" for BOOT, LOOT, etc. Each cued-recall sheet corresponded to one list arranged so that each rhyme cue was followed by 4 lines for recording the responses. The order of the category names for a given list was randomized and was unrelated to order of appearance during input, but the order of the lists corresponded to that used at input.

Subjects. Eighteen *S*s were assigned to each of the 8 between-*S*s treatments, making a total of 144 *S*s. These *S*s were assigned in blocks of 8, with 1 *S* from each condition per block. Assignment within blocks was determined by a table of random numbers. All *S*s were selected from introductory psychology courses and received points toward their grades for participation. Each of 3 female *E*s ran one-third of the *S*s in each treatment so that *E* was balanced with respect to all conditions.

Results

Separate analyses of variance were performed on immediate recall within each list condition, including a separate breakdown for type of recall. All of these analyses showed that type of recall was insignificant, attesting to the comparability of the free- and cued-recall groups on immediate recall. The mean number of words recalled per list, with the data pooled across all lists in the 8 groups, was 13.86. All deviations from this value, for all lists and conditions of recall, were less than one word. Similar analyses of variance were performed on categories and on words/category. For both of these measures, all analyses indicated that type of recall was insignificant and that recall per list was constant. The mean number of categories per list represented in immediate recall was 4.95, and the mean number of words/category was 2.80.

The results of a clustering analysis of the immediate recall data were consistent with the supposition that rhyme categories can serve as functional units of memory. Ratios of number of items recalled in clusters to total recall were calculated with a cluster defined as at least 2 adjacently recalled rhyming words (Marshall, 1967). These values indicated that nearly all of the words were recalled in rhyme groupings, and that this tendency was not affected by amount of practice. For example, for *S*s learning 6 lists, 89% of the words recalled from the first list were recalled in categories and 86% of the words recalled from the sixth list were recalled in categories. To the extent that *S*s attempted to recall the list in terms of order of input, these values would tend to overestimate the degree of clustering. Nevertheless, each list was presented in 3 different input orders prior to immediate recall, a procedure that should have discouraged the utilization of a seriation strategy.

One of the principal findings of this experiment was that the words/category measure, in addition to the word and

TABLE 1

Mean First-List Recall of Words, Categories, and Words/Category for the First Total Free-Recall Test

Measure	Number of lists			
	1D[a]	1	3	6
Words	11.00	12.58	6.36	4.50
Categories	4.11	4.56	2.53	1.80
Words/category	2.56	2.73	2.55	2.11

[a] The abbreviation 1D = one-list delay condition presented to control *Ss*.

category recall measures, varied as a function of the number of interpolated lists. Table 1 displays mean recall of words, categories, and words/category from the first list learned as a function of number of acquired lists. These data were obtained from the first total free-recall test. Separate analyses of variance indicated that number of lists learned was a reliable source of variance for words, F (3, 140) = 34.86, $p < .01$, categories, F (3, 140) = 40.37, $p < .01$, and words/category, F (3, 140) = 3.93, $p < .05$. Fisher's least significant difference (LSD) values for each of these respective measures were 1.79, .57, and .38. Thus, the results of these analyses confirm the obvious trends displayed in the table. Significant and increasing amounts of retroaction on the initial list were obtained, for every performance measure, as the number of interpolated lists was increased from 0 to 2 to 5. [illegible]ther-more, performance on 1D fell betw[illegible] that obtained for the 1- and 3-list co[illegible]ions. However, even though the passag[illegible] time resulted in some apparent forge[illegible], the magnitude of this loss was small [illegible]lative to that produced by retroaction.

Table 2 presents the mean n[illegible]r of words recalled per list on the fir[illegible]d on the second total recall tests. [illegible]arate analyses were performed for each [illegible] condition with type of recall as a betw[illegible]en-*Ss* factor and with order of recall an[illegible] when appropriate, with list position a[illegible]ated measurements variables. Since [illegible]nclusions reached by within-*Ss* com[illegible]sons were identical to those reached [illegible] between-*Ss* comparisons, only the lat[illegible] will be discussed. These analyses all r[illegible]vealed significant Type of Recall × Order [illegible] Recall interactions: For the 1D, 1, [illegible] and 6-list conditions, the obtained Fs [illegible] this interaction were, respectively, F [illegible] 34) = 12.83, 8.23, 29.56, and 63.10, p [illegible] .01. Each of these interactions indica[illegible] that the facilitating effects of cuing w[illegible] obtained for only the second total recall test, and hence, these analyses attested to the comparability of the free- and cued recall groups on the first total recall test. The sizable amounts of retroactive inhibition obtained in first total recall for both free and cued groups and in second total recall for the free group were completely elimi-

TABLE 2

Mean Number of Words Recalled on the First and Second Total Recall Tests

[illegible] and type of recall	1	2	3	4	5	6	M	[illegible] 1	2	3	4	5	6	M
1D[a]														
Free	11.22						11.22	11.50						11.50
Cued	10.78						10.78	13.40						13.40
1														
Free	12.50						12.50	13.00						13.00
Cued	12.67						12.67	15.56						15.56
3

Cued	4.39	6.61	[illegible]	6.72	8.33	10.11	7.40	12.44	10.61	11.61	12.39	11.89	10.50	11.57

[a] The abbreviation 1D = one-list delay condition presented to control *Ss*.

nated within a given list condition by providing higher order rhyme cues. In the 6-list condition the facilitating effects of cuing were greater on earlier lists. The *Ss* in the free-recall group recalled an average of 4.89 items from the first list and those in the cued-recall group recalled an average of 12.44 items from this list, a difference of 7.55 items. This difference was gradually reduced, because of decreasing amounts of retroaction in the free-recall groups, until eliminated on the sixth list. The effect was reflected in a reliable Type of Recall × Order of Recall × List Position interaction, F (5, 170) = 3.31, $p < .01$. Fisher's LSD value, based on the pooled between–within error term, was 2.60. It should be noted that although cuing eliminated retroaction within a given list condition, comparison of the column means for cued recall indicated that retroactive effects were still present. Whereas Tulving and Psotka found that cuing restored recall to its original levels, the levels attained in this experiment were still below those of immediate recall.

Since the categories measure showed essentially the same pattern of results as the words measure, a table parallel to Table 2 was not presented. Instead, for all 3 measures, performance was pooled across list position, and the data were analyzed with number of lists and type of recall as between-*Ss* factors and with order of recall as a within-*Ss* factor. The results of these separate analyses indicated that the Type of Recall × Order of Recall interactions were significant for words, F (1, 136) = 95.80, categories, F (1, 136) = 199.58, and words/category, F (1, 136) = 28. 31, $ps < .01$. These interactions are displayed in Table 3. Fisher's LSD values for between-*Ss* comparisons for each of these respective measures were 1.20, .29, and .18; for within-*Ss* comparisons, these values were .46, .18, and .08. The patterns of mean errors for words and for categories indicated that, for both within-*Ss* and between-*Ss* comparisons, significantly more items were recalled on the second recall test when recall was cued. These

TABLE 3

MEAN RECALL OF WORDS, CATEGORIES, WORDS/CATEGORY, AND INTRUSIONS/CATEGORY ON THE FIRST AND SECOND TOTAL RECALL TESTS

Measures	Order of recall tests			
	First		Second	
	Free	Cued	Free	Cued
Words	10.27	9.70	10.53	13.21
Categories	3.89	3.58	3.89	5.41
Words/category	2.53	2.62	2.65	2.42
Intrusions/category	.37	.38	.42	.64

facilitating effects were somewhat greater in the 3- and 6-list conditions than in the ID and 1-list conditions. The *F*s for the 3-way interactions were F (3, 136) = 2.50, $p < .08$, and F (3, 136) = 3.16, $p < .05$, respectively, for the words and categories measures. For the words/category measure, the means presented in Table 3 show that the directions of these effects were reversed. Significantly *fewer* words/category were recalled on the second test when recall was cued. Unlike conceptual category cues, rhyme cues failed to generate the majority of correct instances stored within particular categories. These results suggested that the retroaction displayed in Table 2 was the result of the loss of higher order units as well as the apparent loss of instances within those units. The increment in words recalled under cued recall, and the consequent elimination of retroactive inhibition within a given list condition, apparently occurred because *Ss* were recalling words from more categories, not because the rhyme cue provided access to the majority of correct instances within a given category.

This failure of the cue may have resulted because of difficulty encountered in discriminating intralist and extralist instances within rhyme categories (e.g., Bower, Clark, Lesgold, & Winzenz, 1969). If this supposition is correct, then extralist intrusions per category ought to be greater under conditions of cued as compared with free recall. To check on this possibility extralist intrusions/category were tabu-

lated for recalled categories (i.e., at least one correct instance had to be recalled from the category). Nearly all *S*s exhibited these intrusions. The results of the statistical analysis indicated that the Type of Recall × Order of Recall interaction was significant, F (1, 136) = 9.96, $p < .01$. This interaction effect, which is displayed in the bottom row of Table 3, indicated that significantly *more* intrusions/category were obtained under cued-recall conditions. Sixteen percent of the items recalled per category in the cued-recall conditions were intrusions. Fisher's LSD values for within-*S*s and between-*S*s comparisons were, respectively, .08 and .13. These findings suggested that the rhyme cues provided access to the category as a unit, and that the loss of instances within the unit may have been produced by the difficulty of discriminating between intralist and extralist instances within that unit. In fact, pooling the results for the words/category and intrusions/category measures indicated that items recalled per category was a constant of approximately 75% for all conditions, a value similar to that reported by Tulving and Psotka (1971). An analysis of variance of these pooled measures indicated that none of the sources of variance was statistically reliable, indicating that items/category was relatively invariant.

Discussion

The results of this experiment can be described by summarizing 3 major findings. First, the physical properties of words, in this case their visual-phonetic characteristics, can be used to subjectively organize words already represented in memory. That is, rhymes, like conceptual categories, apparently can function as higher order memory units. Second, the retroactive inhibition in free recall of lists organized into rhyme categories represents a decrement in the recall of these higher order units as well as instances within recalled units. Retroaction effects on the first list were evident within all measures of recall performance: words, categories, and words within recalled categories. Finally, these retroaction effects reflect both inaccessibility of higher order units and unavailability of instances within those units. Providing retrieval cues in the form of rhyme endings provided efficient access to stored information, essentially eliminating retroactive effects. However, retention was not restored to the level attained in immediate recall, and the recall of correct instances within recalled categories actually decreased when relevant cues were provided.

The findings associated with the loss of rhyme categories and the subsequent elimination of retroaction when these higher order units were provided at recall parallel findings associated with conceptual categories as reported by Tulving and Psotka (1971). The losses obtained for instances within recalled categories contrast with the invariance obtained for this measure when instances belong to conceptual categories. In the case of rhymes, instances appear to have been lost from the store since they are "unavailable" even when a highly relevant cue has been provided to aid their retrieval. This loss may have occurred because of the difficulty of making discriminations between prescribed and extralist instances. The rhyme cues are presumed to be effective higher order retrieval aids providing access to the category of relevant words. This effectiveness may (Tulving & Thompson, 1973) or may not (Bahrick, 1970) be determined by what information is encoded during the study trial. However, it is assumed that the cue initiates a search through relevant instances. For each retrieved instance a decision is made as to whether the item was or was not from the list (Anderson & Bower, 1972). The *S*s reportedly experienced little difficulty in generating instances from the category cue and many indicated that they simply matched word beginnings to the rhyme endings, often by going systematically through the alphabet. Accordingly, what is apparently lost from storage is the ability to remember what items of the category appeared in the list and what items did not. This explanation accounts adequately for the facilitating effects of cuing with word endings and for the extralist intrusion findings associated with the experiment. To account for the invariance in words/category obtained with conceptual categories and for its absence with phonetic categories, it must be assumed that greater relative difficulty is encountered in differentiating instances defined by rhyme than in

differentiating instances defined by conceptual relations. A logical analysis of the 2 types of "categories" attests to the reasonableness of this assumption. Each instance of a rhyme category literally recapitulates the category itself, e.g., "OOT" is contained in BOOT, ROOT, etc. Hence, all instances are directly part of the category and, for that matter, all instances are directly related to each other since, by definition, to be a member of the category requires the sharing of identical physical features. Each exemplar of a conceptual category is associatively related to the category name but recapitulates it only by virtue of the strength of this associative relationship and, furthermore, the instances within the category may or may not be associatively related.

One implication of this interpretation is that similar mechanisms may be involved in the acquisition and retention of lists containing conceptually defined categories and lists containing rhyme-defined categories. Whether the results indicate that words/category is invariant may simply be dependent upon the degree of relatedness of the instances falling within the category. If this interpretation is correct, then invariance of words/category may not be obtained if only some portion of the items of an exhaustive conceptual category are used since items within these types of categories tend to be highly related (e.g., Cohen, 1963).

CODING AND VARIED INPUT VERSUS REPETITION IN HUMAN MEMORY[1]

HENRY C. ELLIS,[2] FREDERICK J. PARENTE, AND CRAIG W. WALKER

University of New Mexico

Two experiments examined the effects of constant vs. varied input of letter strings on recall and recognition memory. Letter strings constructed from pairs of trigrams were fractionated or spatially grouped and presented as either a constant or varied grouping on successive presentations. Varied input produced much greater recall of the entire letter sequence than did constant input. Presumably, *S*s in the varied condition were more likely to adopt a strategy of looking for and encoding a larger unit or structure than *S*s in the constant condition, a strategy which facilitates recall. In contrast, recognition was enhanced by constant input of the letter sequences, a finding predictable from simple frequency considerations.

The following experiments concern the role of nominal-stimulus variation vs. constant or fixed input on recall and recognition memory for groupings of letter sequences. A classical assumption in human memory has been that repetition of stimulus events, in the sense that nominal stimuli are presented in the same manner or form on successive study trials, results in superior memory compared to conditions in which nominal stimuli are varied in some fashion. Nominal-stimulus variation has generally referred to situations in which contextual and/or structural variations of stimuli are introduced in the course of learning.

This assumption has been recently challenged by Bevan and his colleagues in several experiments which have shown that variation among instances of stimulus categories could increase the likelihood of recall. In one study (Dukes & Bevan, 1967), stimuli of the class ax, bx, cx, dx, etc., were presented, where x was the common feature and a, b, c, and d were the modifying elements. For example, x represented a photograph of a particular person, and a, b, c, or d represented his appearance in different poses or dress. To each stimulus compound of a given class *S*s learned a particular name response and then were tested for recall of that response when shown either one of the training stimuli (e.g., bx), or new instances of the category (e.g., jx). They found that the superiority of varied training depended upon whether the test stimulus was a truly old one vs. a "new" item from the category employed. Specifically, when the stimuli were varied during training, varied training produced superior cued recall (using either old or new stimulus items) compared with repetition training (using only new stimulus items). In contrast, repetition training always produced superior recall compared with all other conditions when the test stimuli were old.

Although these results place constraints on any simple generalization about the superiority of varied training, a similar study (Bevan, Dukes, & Avant, 1966) using free-recall procedures indicated that the free recall of generic stimuli (e.g., "pine tree," "oak tree") increased as a result of varied context with both pictorial and word stimuli. Nevertheless, the superiority of varied training was quite small, although reliable, and attempts by Goggin to replicate this finding with word stimuli have not been successful (J. Goggin, personal communication, March 1971).

An alternative approach (e.g., Bower & Winzenz, 1969) is to vary directly the structural properties of the *entire* stimulus to be placed in memory as distinct from varying the modifying elements. The

tudies by Bevan (Bevan et al., 1966; Dukes & Bevan, 1967) have varied only modifying features, making them in sense concept identification studies cause a common relevant cue is always ent in the stimulus compound; the ulus context is varied, whereas the be-recalled response term is kept con- nt. This distinction differentiates be- en 2 kinds of variation, which may e different effects on memory: variation posed on the entire event or sequence be remembered vs. variations in only contextual stimuli present during t aining.

The purpose of the present experiment was to exploit the second approach by varying the grouping structure of pairs of trigram doublets (e.g., DENGIT) and to determine the effect of constant vs. varied presentation of grouping structures on recall and recognition. Bower and Winzenz (1969) have reported that variation of the grouping structure of digit series presented auditorily leads to severe degradation of recall and recognition performance. Only when the digit series were grouped in a constant fashion on successive trials did improvement in memory result. The digit series lacked, however, any evident "inherent" overall structure that might be detected by *S*, since they were random permutations of digits. This is simply to say that a string such as *391*, *87*, *625* is no better a 3-chunk set than is *39*, *1876*, *25*, or vice versa; there is no inherently better combination of the numbers for *S* to seek. In this instance, stability rather than variability of the *E*-imposed grouping structure was essential for memory improvement.

It is reasonable to examine the effect of constant vs. varied input under conditions in which an existing structure is present in the series. Structure is used here simply to refer to natural groupings of letters, pronounceable groupings, or easily integrated units. If an inherent (preexperimentally developed) structure is present, as well as detectable by *S*, then it is conceivable that varied input, in the sense of changes in grouping structure on successive presentation, may facilitate recall of the letter series. This finding could result from the modification of *S*'s search strategy in looking for groupable letter sequences. This is simply to suggest that varied input may lead *S* to achieve *S*-imposed encodings, based upon the existing overall structure, more rapidly than would occur with constant input. In contrast, *S*s receiving constant input of letter sequences may be more likely to process them as presented by *E*, and in so doing, they would be less likely to detect codings that would enable a high level of recall. Trigram doublets such as CUPNET or CIMBUX contain an easily recallable structure, if detected, and thus the recall of a series of letters, even when "fractionated" according to different grouping rules on successive presentations, may be enhanced by varied grouping of the sequence. Constant input in this experiment refers to a given doublet such as CUPNET being presented, for example, as C UPN ET consistently on successive presentations, whereas varied presentation refers to changes in the grouping structure on successive presentations, such as C UPNE T on one and CU PN ET on another.

Experiment I examined the effects of constant vs. varied input on recall of letter groupings and indicated that varied input produced superior recall. Experiment II examined the effects of input structure on recognition memory and revealed that constant input produced superior recognition, a finding predictable from simple frequency considerations. In both experiments, 3 levels of trigram meaningfulness (*m*) were employed in order to examine the effects of varied–constant input as a function of *m*.

Experiment I

Method

Design. The *S*s were 30 undergraduate student volunteers from the University of New Mexico. Each *S* received 8 study–test trials to learn and recall a mixed list of 12 trigram doublets. A constant and a varied condition of stimulus presentation were employed. In the constant condition, the doublets were presented consistently on each study trial. In the varied condition, *S*s saw different perceptual groupings of each doublet on successive lists presented within a trial. Inter-

spersed between each study trial was a test trial in which S was required to recall the entire sequence of 6 letters in the order and sequence in which they were presented.

Stimuli. The stimulus items were trigram doublets constructed by combining 2 trigrams of comparable m values selected from the Archer (1960) norms. For example, the trigrams RUM and WIG were combined to form the doublet RUMWIG. The average association values for the 4 high-, moderate-, and low-m trigram doublets were 100%, 56%, and 12%, respectively. Doublets used were RUMWIG, DENGIT, BANCOW, CUPNET, CIMBUX, JUMHYR, PUZWEK, SUBTYC, TIJFEQ, NEJWOQ, YIWFEP, and MOJZUV. Each of the doublets was fractionated (spatially grouped) into 3 groupings of letters according to one of 4 grouping rules. For example, the 4 high-m doublets, RUMWIG, DENGIT, BANCOW, and CUPNET, once fractionated were presented as groupings of R UMWI G, DE NGI T, BA NC OW, and C UPN ET, respectively. The 4 moderate-m and 4 low-m stimuli were also fractionated according to the same rules.

Four stimulus lists were prepared, each list containing the 12 fractionated stimuli presented in a different serial order. In the constant condition, each doublet was presented in the same fractionated fashion over successive presentations of the lists. In the varied condition, the doublets were fractionated according to a different rule over successive presentations of the 4 lists. For example, the doublet BANCOW appeared as B ANCO W, B ANC OW, BA NC OW, and BA NCO W, on each list, respectively. Thus, the grouping rules specify letter groupings as follows: 1, 4, 1; 1, 3, 2; 2, 2, 2; and 2, 3, 1. Variation of the nominal stimulus was thus defined in terms of the use of a different fractionation rule applied to the same doublet on successive list exposures. Moreover, the intact trigram (e.g., BAN or COW) was never presented in either the varied or constant condition. The letters of a given doublet were always presented in the same order and sequence for both conditions, despite changes in the grouping structure for the varied condition.

Procedure. There were 8 study–test trials administered in each condition, a trial consisting of the successive presentation of 4 stimulus lists of the 12-doublet letter strings. Thus, S saw a total of 48 (4 Lists × 12 Doublets) stimulus presentations per trial. Each fractionated doublet was exposed for a 2-sec. interval on a Stowe memory drum, and S was instructed to remember the items, as he would be tested for recall. Since S saw each doublet fractionated 4 ways in the varied condition, input variation occurred *within* each trial; on successive trials, the same 4 varied versions were repeated.

The Ss were given a recall task interspersed between each trial that required them to recall the letters in the order and sequence presented. The Ss were given a test sheet containing 12 horizontal arrangements of 6 adjacent boxes, and S filled in each arrangement of boxes with the appropriate stimulus letters. The Ss were i[illegible] to fill in all of the boxes (guessing unknown [illegible] whether or not they were sure of their r[illegible] making the procedure one of forced reca[illegible] though the task required that the letters b[illegible] in the order and sequence in which th[illegible] shown, Ss were allowed to free recall the let[illegible]

Results

Recall. The principal data obtai[illegible] in recall are shown in Figure 1, whic[illegible] a plot of the probability of correct com[illegible]ete recalls (all 6 letters in correct ord[illegible]nd sequence) for the constant and vari[illegible] input conditions over 8 trials. The [illegible]ure shows a substantial superiority in [illegible]ecall due to varied input throughout the test sequence, F (1, 28) = 12.90, $p < .005$. Terminal recall probabilities for the v[illegible]ried and constant conditions were .73 and .43, respectively. Recall improved for [illegible]oth conditions as a result of practice, F (1, 196) = 81.08, $p < .001$, and the rate of improvement was faster under the va[illegible]ied condition, as reflected in the significant Type of Training × Trials interaction, F (7, 196) = 10.89, $p < .001$. The effect of meaningfulness was also significant, F (2, 56) = 58.73, $p < .001$. Mean probabilities of recall in the varied condition for the 3 levels of meaningfulness (high, moderate, and low) were .70, .45, and .4[illegible], respectively, whereas the comparable means of the constant condition were .41, .21, and .11, respectively. Since meaningfulness did not interact with type of training, F (2, 56) = .67, $p > .20$, separate recall figures showing this effect are not shown. The data of Figure 1 are thus based upon all levels of meaningfulness.

Partial recall of sequences. Partial recalls of 5-, 4-, 3-, and 2-letter strings were calculated in order to examine the effect of varied-constant input on size of the recalled chunk. A partial recall was defined as the correct recall of 2 or more *adjacent* letters. Thus, a correct partial recall of a 3-letter sequence (unit) for the trigram RUMWIG would be, for example, RUM, UMW, MWI, or WIG. A given recalled sequence was scored only once, so there were no duplicate or nonindependent scorings. For example, a partial recall of RUMW was

·d as 1 4-unit recall, not as 2 3-unit lls or 3 2-unit recalls. As expected, varied group gave more 4- and 5-unit ings, F (1, 14) = 11.82, $p < .005$, reas the constant group gave more and 3-unit strings, F (1, 14) = 52.2, .001. This trade-off is necessary, ce the higher recall of 2- and 3-unit ings for the constant group is due to fact that the varied-group *S*s use up eir potential 2- and 3-unit strings in eir more frequently recalled 4- and 5-unit ·ings.

Single-letter recall. A third recall meaure, the total number of correct singletter recalls, was calculated. Single-letter ecalls were again scored only if they were n the correct serial position, and each recall was scored correct or incorrect regardless of the recall of an adjacent letter. Thus, on a given trial there were 72 possible correct single-letter recalls (12 Trigram Doublets × 6 Letters per String). The mean correct single-letter recalls, averaged over 8 trials, were 49.9 for the varied condition and 31.3 for the constant condition, F (1, 238) = 62.44, $p < .001$. This simply indicates that the superiority of the varied condition in recall holds regardless of whether single letters or the entire sequence of 6 letters is the scoring unit.

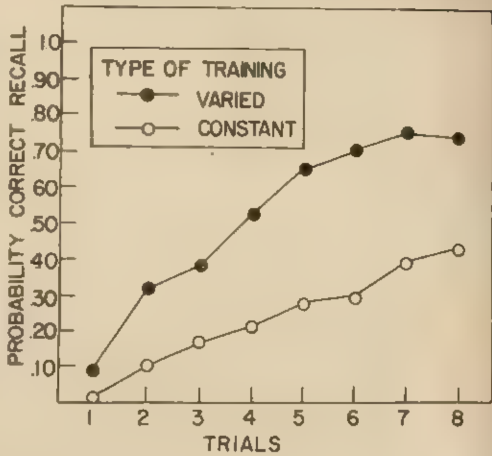

FIGURE 1. Probability of complete recall of the letter sequences as a function of trials, with varied vs. constant input of letter groupings as parameter.

EXPERIMENT II

The second experiment examined the effects of varied vs. constant training on recognition memory where it was proposed that nominal-stimulus variation would lead to poorer recognition performance.

Method

Design. The *S*s were 34 undergraduate student volunteers from the University of New Mexico. The *S*s were given training with varied or constant presentations as in Experiment I, followed by a 2-item forced-choice recognition test. Three modifications of the training procedure were introduced. The study trial consisted of only one presentation of the list (rather than 4), followed by the recognition test. Thus, in the varied condition, *S* saw a different list on each trial for a block of 4 trials. Twelve study trials were administered (rather than 8), with lists varied within blocks of 4 trials. Thus, *S*s in the recognition experiment were given 12 presentations/trial for a total of 144 presentations (12 Items × 12 Trials), whereas *S*s in the recall experiment were given 48 presentations/trial for a total of 384 presentations (4 Lists × 12 Items × 8 Trials). This was done simply because it was unnecessary to provide as much training in the recognition experiment. Each fractionated doublet was presented for only 1 sec.

Procedure. The experiment again used a study–test procedure. After each study trial, *S*s were shown the old stimuli singly, paired with a highly similar distractor item. Distractors were formally similar to the old (target) items, with a distractor consisting of a 1-letter substitution of one of the 4 middle letters of the old doublet. A vowel was replaced by a vowel and a consonant was replaced by a consonant. For example, the old item R UMWI G was paired with the distractor R AMWI G on one trial and R UMNI G on another trial, for the constant condition. Thus, an old item and its distractors retained the same fractionation rule on study and test trials in the constant condition. A different distractor item was used on each of the 12 trials, and the right–left position of the pairs was randomly varied on each trial. The *S*s were instructed to underline whichever item in the pair they had seen during the study trial. The procedure was the same for the varied condition except that the distractor items were fractionated according to the same rule as the old item as it appeared on a given study trial. Thus, on a given recognition test, R AMWI G was paired with R UMWI G, and on a subsequent test, RU MN IG was paired with RU MWI G.

Results

Recognition. The principal data obtained in the recognition test are shown

in Figure 2, which is a plot of probability of correct recognition over test trials. This figure shows that constant training leads to superior recognition compared with varied training, $F\ (1,\ 32) = 15.16$, $p < .001$. Terminal probabilities of correct recognition for the constant and varied conditions were .90 and .80, respectively. Recognition improved for both conditions as a result of training, $F\ (11, 352) = 14.54$, $p < .001$; however, there was no reliable Type of Training × Trials interaction, $F\ (11,\ 64) = 1.20$, $p > .20$. The effect of meaningfulness was also significant, $F\ (2,\ 252) = 38.18$, $p < .001$. Mean recognition performances in the constant condition for the 3 levels of meaningfulness (high, moderate, and low) were .85, .85, and .73, respectively, whereas the comparable means for the varied conditions were .75, .73, and .63 respectively. Again, since meaningfulness did not interact with type of training, $F\ (2, 64) = 1.23$, $p > .20$, only a single recognition plot is presented.

Discussion

The principal findings of the experiments were that varied input, in the form of altered groupings of letter sequences taken from trigram doublets, facilitated recall of the letters, whereas constant input facilitated stimulus recognition. The superiority of varied input on recall occurred whether measured by complete recall of all letters in the appropriate position or by total number of correct single-letter recalls. Thus these data indicate one restriction on any assumption that sheer repetition of stimulus events is the condition for achieving maximum recall.

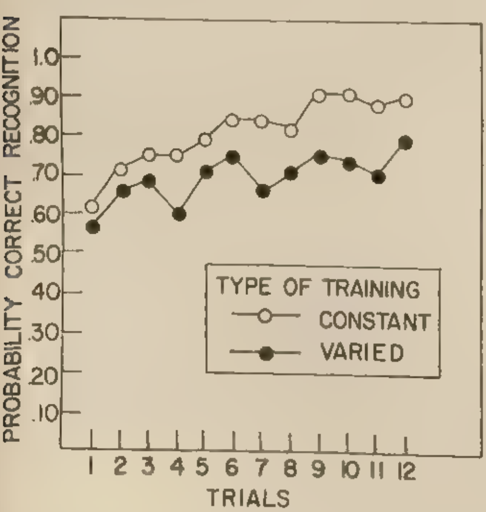

FIGURE 2. Probability of correct recognition of letter sequences as a function of trials, with varied vs. constant input as parameter.

An explanation of the general superiority of varied input on recall is reasonably straightforward and can be accounted for by what we call a *perceptual regrouping hypothesis.* The process is viewed as operating in the following manner. When S is shown varied groupings on successive presentations, he eventually learns to ignore the E-imposed groupings, since they change on successive presentations and are not a relevant feature. In addition, it is assumed that varied input leads S to adopt the strategy of seeking a new and overall grouping which, if successful, will facilitate recall because the particular letter sequences used can be grouped as a unit. Since the letter sequences contained an inherent grouping structure in the form of pronounceable or easy-to-integrate units, detection and encoding of this overall structure must facilitate recall. Moreover, the recall data suggest the general principle that variability in nominal-stimulus input leads to greater stability in S's functional encoding under conditions in which S can achieve an overall or unitary encoding of the input sequence. In contrast, if no existing or inherent structure were present, varied input would not be expected to facilitate recall. Search for such a structure and the corresponding development of S encodings would be fruitless, and performance in such instances would be degraded.

On the surface, the superiority of recall under varied input appears contrary to the results reported by Bower and Winzenz (1969) and may further imply that their reallocation hypothesis is limited. Critical differences between the experiments appear, however, to make the superficially divergent results understandable. The perceptual regrouping hypothesis can account for differences between this experiment and Bower and Winzenz's Experiments I and II regarding recall, where in the latter study it was necessary for S to have a stable E-imposed structure for learning to occur. Moreover, a stable E-imposed structure was necessary for learning even when letter sequences were used (Winzenz, 1972, Experiment V), if the groupings themselves

ıf words. The perceptual regrouping ьesis assumes only that varied input in m of letter groupings, instead of being .ed to separate storage locations, even- ·omes to be regrouped as an integrated nd is then shunted to the same storage on. The point is that *S* must discover a encode a sequence that contains an in- h .nt structure if variable input is to enhance

ere are other differences between these riments, including length of series and ınt of information processed prior to each In addition, differences in auditory vs. ıal presentation may have contributed to pattern of differences in recall between 2 studies. In the present experiment, saw the entire letter sequence and would esumably have greater opportunity to en- ode it as an integrated unit. In contrast, wer and Winzenz (1969) presented the git series auditorily, either as single digits ing read with pauses between groups, or as successive numerical groupings being named. n either instance, auditory presentation ould appear to reduce the likelihood of *S* detecting a larger structure or grouping even if such structure had been present. In short, although there is no doubt that the consistency of *E*-imposed groupings is necessary for improvement in recall under conditions examined by Bower and Winzenz, structural variability of letter sequences aids recall under conditions in which *S* can detect and encode an underlying structure consisting of the entire unit. More generally, these findings further attest to the significance of encoding processes in human learning and memory and to the importance of structural properties of stimuli in learning tasks (cf. Ellis, 1973).

The superiority of recognition under constant input is predictable from relatively simple frequency considerations. The recognition task does not require integration or organization of the letter string into a larger unit. Moreover, the test compared distractors conforming to the same grouping rule as the old items, so that *S* did not have to attend to or encode the particular grouping in the constant condition. Thus, the variable condition reduces the likelihood that *S* will develop a stable encoding *necessary for recognition.* Since the recognition task requires a choice between 2 grouped sequences, *S* would be less disposed to develop unitary encodings in the recognition task. All that would appear to be necessary for correct recognition is the development of a relatively stable encoding which is maximized under conditions of consistent presentation of a fixed structure.

The positive relationships between meaningfulness and recall and between meaningfulness and recognition (Ellis, Parente, & Shumate, in press; Ellis & Shumate, 1973) is well-established and is of no great interest here. What is of interest is the lack of an interaction between varied–constant input and meaningfulness in recall. Although the superiority of the varied condition occurred across all levels of meaningfulness, it might have been expected that the effect would have been attenuated at lower *m* levels, since these items are less easily unitized. Since this did not occur, it would seem reasonable to assume that even low-*m* trigram doublets possess sufficient inherent structure for the variability effect to appear.

Finally, these experiments indicate that variably grouped presentations of letter sequences affect recall and recognition differentially. This outcome is not readily handled by a strength theory of recall and recognition (cf. Kintsch, 1970), which assumes that recall and recognition involve essentially the same processes. The fact that varied input affects recall and recognition in different ways suggests that different processes may underlie the 2 performances. Some caution must be used in making this inference, however, because the 2 training procedures were not exactly comparable, with different amounts of practice, different stimulus durations, and differences in manipulating variability (within trial in recall and between trials in recognition). Despite these differences, the effect of variability was reversed for the 2 conditions over the entire training testing sequence.

ENCODING AND RETRIEVAL PROCESSES IN LONG-TERM RETENTION

AXEL GÖTZ AND LARRY L. JACOBY [1]

Iowa State University

Retention effects of retrieval practice and of predictability of recall delay were investigated in 2 experiments. Several 5-word lists were recalled initially after no delay or delay filled with number subtraction; delay type was predictable for *S*s in a precue but not in a postcue condition. Words from all lists were tested in final free recall (FFR). The advantage of filled over no delay in FFR was greater in the precue than in the postcue condition. This result was taken as evidence that attributes selected for encoding depended on the type of delay anticipated. In Experiment II only half of the lists were recalled initially. Initial recall aided FFR more for filled- than for no-delay words. It was concluded that retention benefits from initial retrieval to the extent that retrieval cues used at initial and final recall are similar.

[illegible]earsal has been used extensively as a[illegible]lanatory concept in recent analyses o[illegible]ory processes. In Atkinson and [illegible]'s (1968) 2-store theory of memory, re[illegible]l serves the dual purpose of main-ta[illegible] items in short-term store (STS) and o[illegible]ermining the amount of information ab[illegible] an item transferred to long-term st[illegible] LTS). Serial position effects in-clu[illegible]ing the negative recency effect found in final free recall (FFR), have been interpreted in terms of the positive relationship between rehearsal frequency and transfer to LTS (Atkinson & Shiffrin, 1971; Craik, 1970). More recent results suggest, however, that rehearsal might only serve the function of maintaining items in STS (Jacoby, 1973; Jacoby & Bartz, 1972; Meunier, Ritz, & Meunier, 1972). In the Jacoby and Bartz study, 3 groups of *S*s were presented with several 5-word lists; each list was recalled initially, either immediately after its presentation, after a silent-delay interval, or after a delay filled with number subtraction. Initial recall int he subtraction condition was well below that in the other 2 conditions, supporting the contention that rehearsal is necessary to maintain items in STS. However, in an unexpected FFR test for all presented words, recall after silent delays was lower than after number subtraction; amounting to an inverse relationship between rehearsal opportunity and storage in LTS. This and the finding that silent-delay items were not better recalled than no-delay items led to the conclusion that rehearsal frequency does not determine transfer to LTS. As possible explanations for the final-recall advantage of filled-delay items, the authors suggested differential encoding during study and differential retrieval practice at initial recall.

According to the differential encoding interpretation, the coding of items during study was dependent on the nature of delay anticipated. For immediate recall or recall after a silent delay, it would be sufficient to keep list items in STS by means of rehearsal with no necessity to generate more permanent retrieval cues. The *S*s in the subtraction condition were likely to organize items or process them to a "deeper level" (Craik & Lockhart, 1972) to insure that they would be retrievable after the filled delay. Thus, subtraction *S*s generated longer lasting retrieval cues that more likely would be still accessible at the time of FFR. The second interpretation appeals to the influence of retrieval practice on later free recall (e.g., Lachman & Mistler, 1970). Immediate recall or recall after a silent delay might only make use of short-lived retrieval cues such as the acoustic trace

[1] Requests for reprints should be sent to Larry L. Jacoby, Department of Psychology, Iowa State University, Ames, Iowa 50010.

of an item (Tulving, 1968), corresponding to retrieval from STS. In contrast, retrieval after a filled delay might necessitate the use of more permanent retrieval cues. Filled-delay items would thus benefit more from retrieval practice since the retrieval cues employed would be more similar to those accessible at the time of final recall. Since differential encoding is assumed to depend on *S*'s ability to anticipate the nature of the delay interval, removal of this ability should nullify the difference between filled-delay and no-delay items in final recall. Differential retrieval practice would be expected to operate regardless of *S*'s ability to anticipate the nature of the delay preceding initial recall. Predictability of delay preceding initial recall was manipulated in the present investigation in order to separate the effects of differential encoding and differential retrieval.

In Experiment I, short lists were presented and free recalled either immediately or after a period of number subtraction. In a precue condition, *S*s were informed prior to list presentation concerning which of the 2 delay conditions would follow. Thus, they had the opportunity to encode words more permanently preceding a filled-delay interval. Final recall for the precue condition was expected to replicate the earlier reported superiority of filled over no delay. In a postcue condition, information about delay type was not available until after list presentation. Since delay type was not predictable during study, the final recall advantage of filled-delay items should be absent if differential encoding was the only factor responsible for the earlier results. No effect of the cuing manipulation would be expected if only differential retrieval was operative in the earlier experiment.

Experiment I

Method

Materials and procedure. Two sets of 150 words with A and AA ratings were randomly selected from the Thorndike and Lorge (1944) wordbook, and used to form 2 replications of the basic design. Within each set, words were assembled into 30 5-word lists and tape recorded for auditory presentation at a 2-sec. rate. The *S*s' oral recall was recorded by *E*. Half of the lists were recalled immediately (no delay, ND) after their presentation while the other half were recalled after a filled-delay (FD) interval. The sequence of immediate and delayed recall was randomized separately for each of 2 sets of lists. The task employed in FD intervals consisted of auditory presentation of randomly selected 2-digit numbers. Numbers were presented at a 2-sec. rate, with the first number occurring 1 sec. after the last word in a list; 7 numbers were presented within the 15-sec. delay interval. The *S*s were instructed to subtract 1 from each number and say the result aloud prior to the presentation of the next number. For all conditions, the word "go" signaled the beginning of the recall interval; recall was spoken. The 7.5-sec. recall interval was terminated by the word "ready" which preceded the first word of the next list by 2 sec.

The *S*s in a precue condition were informed prior to the presentation of each list concerning the nature of the delay that would follow. A stack of 3 × 5 in. note cards was placed before *S*s in that condition; each list was represented by a card. Printed on each card was either the word delayed or immediate, indicating the nature of delay. Upon hearing "ready" preceding list presentation, *S* read the top card and then placed it next to the stack; the card read corresponded to the list that was to be presented. In a postcue condition, *S*s learned about delay after presentation of each list by hearing either the signal for recall or the first of the 2-digit numbers for subtraction

Following recall of the last list, all *S*s were read 3 sets of 9 digits and asked to recall each set in order. Next, *S*s were instructed to write down all the words they could remember from all lists. Prior to these instructions there was no reason for *S*s to anticipate the FFR test. There was no time limit on the final test. The digit span task was employed as an attempt to minimize the effects of retrieval from STS in FFR.

Subjects and analyses. The *S*s were 20 volunteers from undergraduate courses at Iowa State University; 10 *S*s were assigned to each of the cue conditions according to a prearranged random schedule with the restriction that the ratio of males to females must be constant across conditions. The *S*s were tested individually and received extra course credit for their participation. For each *S*, recalled words were classified according to delay condition and serial position.

Analyses to be reported employed a 2 × 2 × 5 (Cue × Delay × Serial Position) analysis of variance with repeated measures on the last 2 factors; initial and final recall were analyzed separately. Replications were not included as a factor since a preliminary analysis indicated that results did not differ across replications.

Results and Discussion

Initial recall. Recall probability as a function of input position, delay, and cue

condition is displayed in Figure 1. The FD items were recalled at a lower level than ND items, F (1, 18) = 313.67, $p < .001$, indicating that interpolated subtraction interfered with the maintenance of list items in STS. Recall probability was slightly higher in the precue (.74) than in the postcue (.67) condition, F (1, 18) = 4.8[illegible], $p < .05$. The main effect of serial position, F (4, 72) = 14.72, and the Delay × Serial Position interaction, F (4, 72) = 9.[illegible], were also significant ($ps < .001$). Recall probability declined steadily across serial positions in the FD condition while remaining relatively stable in the ND condition.

Final recall. Final recall probability was higher for FD than for ND items, F (1, 18) = 33.[illegible], $p < .001$. As predicted by the differential encoding hypothesis, the recall advantage of FD over ND items was greater in the precue (.18, .06) than in the postcue (.15, .12) condition, F (1, 18) = 9.66, $p < .01$. Overall, recall probability declined across input serial positions, F (4, 72) = 6.51, $p < .001$. Although the appropriate interaction was not significant, the decline across positions was almost totally absent for recall of ND items in the precue condition.

Results of the present investigation provided support for the differential encoding hypothesis. When *S*s could anticipate delay type, FD items were coded in a more permanent fashion than were ND items. Coding of the 2 types of items was necessarily the same when *S*s could not predict delay type; coding when delay was unpredictable appears to have been intermediate to the 2 forms of coding employed in the precue condition. The decline in recall probability across input positions can be attributed to the study of earlier items during the presentation of later ones (e.g., Atkinson & Shiffrin, 1971). The absence of serial position effects when *S*s anticipated an immediate recall test suggests that the cumulative study strategy was primarily used to prepare for delayed recall.

The failure to obtain an effect of delay in the postcue condition can be taken as evidence against the differential retrieval

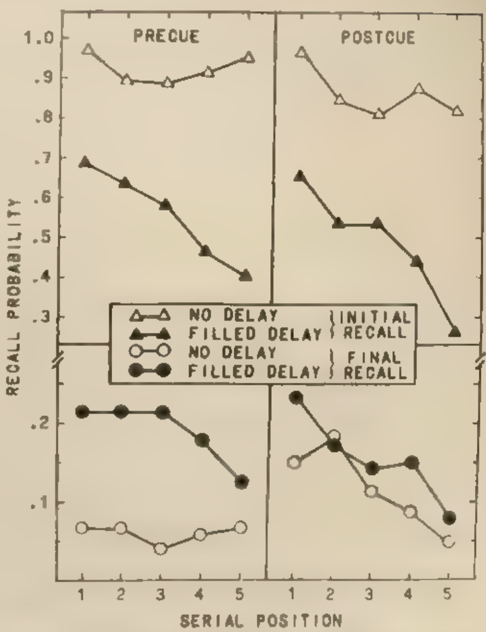

FIGURE 1. Probability of initial and final free recall as a function of serial position, cue, and delay condition in Experiment I.

hypothesis. However, the use of different retrieval cues after the 2 types of delay might develop gradually across the test session. In addition, retrieval cues employed after an FD would at best be expected to be only relatively permanent and might not survive the presentation of a large number of later lists. Both considerations suggest that an advantage for FD items might be more likely in final recall of lists presented near the end of the experimental session. Filled delay and ND in the postcue condition were therefore compared separately for the first 8 and second 7 lists of each type. Final recall probabilities were nearly identical for FD and ND items presented in the first lists studied (.10, .11). However, recall probability from the last study lists was higher for FD than for ND items (.21, .12), t (18) = 2.83, $p < .05$. Thus, the differential retrieval hypothesis cannot be totally dismissed.

Similar comparisons in the precue group reveal higher recall of FD over ND in the first lists studied (.15, .05), t (18) = 3.54, $p < .01$, as well as in the last study lists

(.22, .07), t (18) = 4.78, $p < .001$. Apparently, in contrast to differential retrieval strategies, differential encoding is established early in the course of the experiment.

Experiment II

Experiment II was designed to further separate the effects of differential encoding and differential retrieval. As in Experiment I, *S*s in a precue and postcue condition were exposed to lists followed by either an FD or ND. Now, however, *S*s recalled only half of the lists initially; recall vs. no recall was factorially combined with cue and delay conditions. In all conditions, *S*s were unable to predict whether or not recall would be required. Thus, study encoding should be constant across recall conditions. The effects of differential encoding can be observed uncontaminated by retrieval practice in the no-recall conditions. Comparisons of the final-recall effectiveness of initial recall in the 2 delay conditions yield information that is relevant to the differential retrieval hypothesis. Initial recall after an FD should have a larger effect in FFR if the differential retrieval hypothesis is accurate.

Method

Materials and procedure. A set of 200 words with A and AA ratings were randomly selected from the Thorndike–Lorge (1944) wordbook. These words were assembled into 40 5-word lists and tape recorded for auditory presentation at a 2-sec. rate. The *S*s' oral recall was recorded by *E*. Half of the lists were followed by FD while the other half were followed by ND. Each half was further subdivided into an equal number of lists initially recalled (IR) vs. not initially recalled (NIR). Four delay–recall combinations resulted: FD–IR, FD–NIR, ND–IR, and ND–NIR. Ten lists were randomly assigned to each delay–recall combination; the presentation order of lists was also randomized. Four replications of the basic design were constructed so that each list represented each delay–recall combination equally often. The distractor task employed in FD intervals was the same as in Experiment I, as were the arrangements for recall in the FD–IR and ND–NIR conditions. In the FD–NIR condition, the word "ready" occurred 2 sec. after the last 2-digit number and signaled the beginning of the next list. The word "ready" served the same purpose in the ND–NIR condition but occurred 1 sec. after the last word of the preceding list.

Cuing arrangements for a precue and postcue condition were the same as those in Experiment I. None of the *S*s was precued with regard to recall condition. The recall–no-recall manipulation was explained to *S*s by describing the investigation as being concerned with the effects of disruption on memory. Other procedural details including arrangements for digit span tests and final recall were identical to those in Experiment I.

Subjects and analyses. The *S*s were 40 volunteers enrolled in psychology courses at Iowa State University and received extra course credit for their participation. Twenty *S*s were assigned to each cue condition according to a prearranged random schedule with the restriction that the ratio of males to females must remain constant across conditions.

Study lists were divided into 2 blocks of equal size for preliminary analyses of initial and final recall. The 20 lists of Block 1 were the first 5 lists representing each of the 4 delay–recall combinations while those in Block 2 were the second 5 lists from each combination of conditions. The analysis of initial recall failed to reveal any significant effects of input block. In final recall, the probability of recall was higher for lists presented in the second (.11) than in the first (.06) block, F (1, 266) = 67.94, $p < .001$; effects of other variables were generally consistent across blocks but more pronounced in Block 2. The finding of more pronounced effects in final recall of later presented lists is similar to that reported in Experiment I and may be due to either recency of presentation or the development of study strategies. Since effects in recall of early lists were less clear and did not contribute additional information, results will be reported only for lists presented in Block 2. Initial recall data were treated as in Experiment I. Final recall scores were entered into a 2 × 2 × 2 × 5 (Cue × Delay × Initial Recall × Serial Position) analysis of variance with repeated measures on the last 3 factors.

Since in earlier experiments, including Experiment I, interactions of *S*s with other factors did not reach significance ($p = .05$), it was decided a priori to use the pooled interactions with *S*s as the denominator for F tests. The appropriateness of this procedure was checked for the analyses of initial and final recall. Only 1 of the 8 interactions involving *S*s exceeded the .10 level, F (38, 152) = 1.39, indicating that the assumptions necessary for pooling were met.

Results and Discussion

Initial recall. Initial- and final-recall probabilities for each combination of conditions are plotted in Figure 2. As expected, recall was lower in the FD than in the ND condition, F (1, 342) = 336.70, $p < .001$. The Delay × Serial Position interaction was also significant, F (4, 342)

= 3.7[illegible], $p < .05$. Recall probability declined across input positions in the FD condition while showing a slight increase for ND items. Intrusion errors were infrequent; intrusions from lists that were not recalled were only slightly more frequent ([illegible]2.2%) than those from recalled lists ([illegible].7%). Thus, it appears that *S*s successfully differentiated lists.

Final recall. The effects found in Experiment I were replicated. As shown in Figure [illegible] recall probability declined across serial positions, F (4, 722) = 15.20, p < [illegible] and was higher for FD than for ND [illegible] F (1, 722) = 18.59, $p < .001$. The recall advantage of FD over ND items was larger in the precue (.14, .08) than in the postcue (.12, .11) condition, F (1, 7[illegible]) = 9.68, $p < .01$, again supporting the differential encoding hypothesis. For lists not initially recalled, final recall in the precue condition was higher for FD than for ND items (.10, .05), t (722) = 2.70, $p < .01$. Thus, the effect of differential encoding manifested itself in pure form. Lists that were recalled initially showed higher final recall than did lists that were not initially recalled, F (1, 722) = 29.20, $p < .001$. In addition, the differential retrieval hypothesis predicts that FD items should benefit more from initial recall than should ND items. The corresponding Initial Recall × Delay interaction was significant, F (1, 722) = 4.53, $p < .05$, and showed that initial recall was most beneficial for FD items. As shown in Figure 2, the advantage of FDs was larger in the precue than postcue condition but present in both among items that had been recalled initially. The present investigation thus provided evidence of both differential encoding and differential retrieval.

The results are also relevant to a third possible interpretation of the final-recall advantage of FD items. It might be argued that the subtraction task was not demanding enough to completely eliminate rehearsal, and that the higher final recall of FD items was produced by this additional rehearsal. This interpretation would predict higher recall of FD items even for lists that were postcued and not recalled initially; neither differential encoding nor differential retrieval would predict an effect of delay for these lists. The results showed that final-recall performance was nearly identical for FD and ND items (.09, .10) in the postcue condition that had not been tested initially. Thus, there was no evidence that rehearsal during subtraction aided final recall.

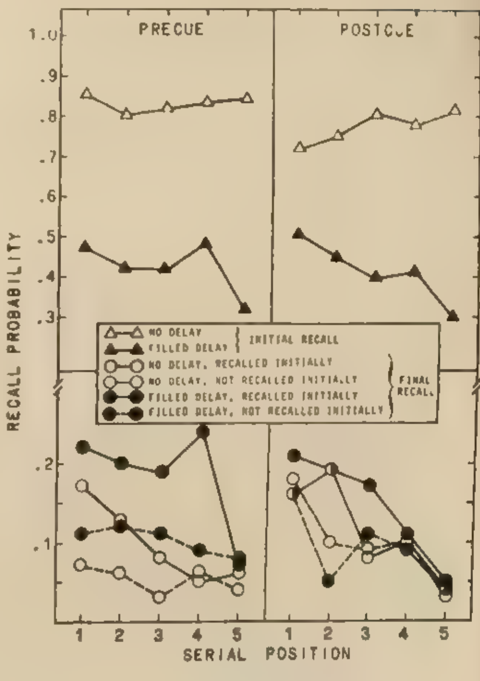

FIGURE 2. Probability of initial and final free recall as a function of serial position, cue, delay and initial recall condition in Experiment II.

General Discussion

Among the most widely observed effects in studies of memory is the dependence of recall probability on study opportunity (e.g., Cooper & Pantle, 1967). One possible explanation of this effect is that rehearsal frequency determines the probability of delayed recall or, in the context of a 2-store theory, the transfer of information to LTS. While the term "rehearsal" has been defined in a variety of ways, it is used in this discussion to denote *S*s' overt or covert repetition of items.

Memory theorists holding widely divergent orientations (e.g., Atkinson & Shiffrin, 1968; Underwood, 1972) have agreed concerning

the central role played by rehearsal frequency. The rehearsal frequency interpretation also has the advantage of parsimony and has been applied to a wide variety of phenomena. Despite its wide acceptance, there is no firm evidence of a causative relationship of rehearsal frequency to delayed-recall probability. The most convincing evidence has come from experiments that have required overt rehearsal and have related rehearsal frequency to recall probability (Atkinson & Shiffrin, 1971; Rundus, 1971; Rundus & Atkinson, 1970). It should be recognized, however, that overt rehearsal only renders observable *S*s' vocalization of study items; rehearsal might be accompanied by considerably more complex processing that is not observable. The relationship of overt rehearsal frequency and recall probability that has been found might be due to the correlation of both factors with underlying coding processes.

Recent evidence suggests that explanations of long-term memory effects in terms of rehearsal frequency are insufficient. Several studies (Jacoby, 1973; Jacoby & Bartz, 1972; Meunier et al., 1972) have found no effect of variations in rehearsal opportunity or frequency of overt rehearsal in long-term memory performance. Moreover, the present investigation found differences in final recall for conditions that were equated with regard to rehearsal opportunity during study; final recall in the precue condition was higher for lists followed by FD rather than ND. It might be argued that the subtraction task employed did not eliminate rehearsal so that the FD condition had additional opportunity for rehearsal. However, further analyses revealed that rehearsal was either absent during delays or did not aid final recall. These results can be accounted for if rehearsal, defined as repetition of items, is assumed to be only one of several types of processing available to *S*s. Rehearsal may be sufficient to maintain items for immediate recall while additional processing is required to aid performance on a long-term memory test (Craik & Lockhart, 1972; Jacoby, 1973).

The trace resulting from the encoding of an item can be conceptualized as a set of attributes, with the level of processing determining the particular attributes included in the set (Craik & Lockhart, 1972). Processing in addition to rehearsal will lead to the inclusion of attributes that are more resistant to loss. If an item is studied under the expectations of immediate recall, its memory trace will contain fewer and less permanent attributes than if it is studied with the anticipation of delayed recall. More permanent attributes are encoded, including organization of list items, when delayed recall is anticipated. Consistent with the preceding statement are *S*s' descriptions of their study activities. When asked after the experiment, several *S*s in the precue condition reported making up sentences, stories, or mental images involving list items when an FD was anticipated, and merely repeating the items when they expected an immediate-recall test. The nature of delay preceding recall was not predictable in the postcue condition. The *S*s in that condition may have either adopted an intermediate level of processing for all lists or vacillated between rehearsing items and attempts to organize them. It should be noted that the relating of processing to *S*s' expectations and cognitive states is not a new development, and gains support from an older literature. Müller (1911, pp. 11–20) listed a number of variables that he found to influence study strategy; the time interval between study and test was among those listed.

Data from the present experiments also provided support for the differential retrieval hypothesis. The final-recall effects of initial recall can be interpreted within the memory attribute framework. Attributes used as retrieval cues experience an increase in cue effectiveness as a consequence. The use of short-lived attributes requires less effort so that they are employed as retrieval cues when there is a choice; immediate recall primarily uses short-lived attributes such as the acoustic trace of an item. If an FD precedes recall, short-lived cues will not be available and initial recall will be based on more durable attributes. Later recall will benefit from initial recall only to the extent that both can use the same attributes as cues. Initial recall after an FD was more advantageous, since the attributes employed for retrieval were more likely to be also available at the time of final recall, than were those used in the ND condition. It would be predicted that the effectiveness of initial recall could be even further enhanced by increasing the duration of the FD interval.

Recall differences observed in the present experiments cannot be explained in terms of amount of study opportunity or rehearsal frequency. Rather, recall performance appears to be a function of the attributes that are accessible at the time of test. Accessi-

bilit[illegible] depends on 2 factors: (*a*) Dif-fere[illegible]oding during study determines whi[illegible]utes are used originally to form the[illegible] an item, and (*b*) the cue effective-ness of attributes is enhanced by their prior use[illegible]eval cues. Long-term recall per-form[illegible]ill be aided by an earlier recall to the[illegible] that the same attributes can be used[illegible]trieval cues on both tests.

VARIED FUNCTIONS OF PUNISHMENT IN DIFFERENTIAL INSTRUMENTAL CONDITIONING[1]

GEORGE T. TAYLOR[2]

State University of New York College at Potsdam

A simple discrimination setting—differential instrumental conditioning—was used to assess the functions of punishment in discrimination learning in a 2 × 2 × 3 factorial design, plus 2 control groups, with 168 rats. The variables manipulated were type of stimulus (tone or shock), presentation of the trials (forced–free or forced), and alley of stimulus presentation (postive stimulus, negative stimulus, or both). The results indicated that shock can serve a variety of functions, e.g., as (*a*) an aversive stimulus, (*b*) a distinctive, informative stimulus, (*c*) a secondary reinforcer, and (*d*) perhaps most interestingly, an alerting stimulus. These findings are interpreted as suggesting that the role of punishment in differential instrumental conditioning is complex.

A response-produced aversive stimulus, i.e., punishment, does not always reduce the probability of a response. A notable example is a study reported by Muenzinger (1934) which demonstrated that, in a discrimination setting, shocking rats in the presence of the positive stimulus (S+) may facilitate learning the discrimination. This finding, the shock–right phenomenon, has generated a large body of data and theoretical speculations which relate to the more comprehensive properties of aversive stimulation.

Muenzinger (1934; Muenzinger & Wood, 1935) interpreted his data as implicating an effect of punishment which was general in nature. The function of noxious stimuli was suggested to be that of alerting the animal so as to make him respond more readily to the significant cues in the learning situation. The general alerting mechanism was proposed to be revealed behaviorally as vicarious trial-and-error (VTE) activity (Muenzinger, Bernstone, & Richards, 1938).

Later, Wischner (1947) questioned the generality of these results and subsequent conclusions, especially with respect to Muenzinger (1934; Muenzinger et al., 1938; Muenzinger & Wood, 1935) using only correction procedures in which the animal must retrace his incorrect responses. Using the noncorrection procedure, Wischner found that punishing the correct response appeared to only slightly facilitate discrimination efficacy relative to a nonshocked group, although the differences between the 2 conditions were small and statistically unreliable. However, though the difference was not as great as that found earlier by Muenzinger (1934), Wischner replicated the basic shock–right phenomenon. Thus, even in the noncorrection paradigm, punishment in the presence of S+ facilitated the discrimination rather than the expected inhibitory effect.

An alternative interpretation of these data emphasized the specific effects of punishment (cf. Fowler & Wischner, 1969). For example, the shock, by virtue of its association with the reward, served as a discriminative stimulus and, therefore, as a conditioned stimulus (Azrin & Holz, 1966). Extending the discriminative stimulus analysis, Fowler and Wischner (1965) have suggested that shock for either correct or incorrect responses served to differentiate the alleys more quickly and thus delimit the generalization between the 2 alternatives. As a result, these authors (Azrin & Holz, 1966; Fowler & Wischner, 1969) have re-

[1] This article is based upon a dissertation submitted to the University of New Mexico in partial fulfillment of the requirements for the PhD degree. The author would especially like to thank Frank A. Logan who served as the committee chairman. The research was performed while the author was a National Institute of Mental Health trainee and was supported in part by National Science Foundation Grant GB-12954 to Frank A. Logan.

jected the general alerting analysis of Muenzinger et al. (1938) and have adopted the position that the facilitative consequence of shock–right training is based upon shock serving as a secondary reinforcer and/or as a distinctive stimulus.

Although these 2 interpretations are not mutually exclusive, and indeed both may be implicated, theorists, in the interest of parsimony, have been reluctant to accept both to account for the shock–right data. It is possible that the resulting controversies (cf. Fowler & Wischner, 1969) stem from the extensive use of the simultaneous discrimination paradigm. This procedure has several disadvantages for an analysis of the effects of shock. First, it enables the animal to compare directly the discriminanda. Thus, if VTE, or some comparable general mechanism, contributes to the shock–right phenomenon, all *S*s had similar opportunities to make such comparisons. Second, and perhaps more importantly, the paradigm provides only one measure of performance, choice behavior. This measure represents the differences between the response strengths of the alternatives, but does not indicate directly which is being affected by the shock.

Accordingly, the present experiment attempted to make a unique contribution by including a simpler discrimination setting—differential instrumental conditioning—in which the discriminable cues are presented singly. This paradigm, therefore, provides a procedure which limits the opportunity to compare the stimuli directly, as well as providing an individual measure of response strength to each alternative. In addition, a more neutral tone stimulus was given to some *S*s to allow an assessment of the aversiveness of shock.

Method

Subjects. The *S*s were 168 female albino rats obtained from a commercial supplier. The experimentally naive *S*s were 90–120 days of age at the beginning of experimentation and were housed individually with water freely available. A daily ration of 12 gm. of laboratory chow was given immediately after each day's experimental session. The *S*s, randomly assigned to 1 of 14 groups with 12 *S*s in each, were run in replications of 2 *S*s per cell; each treatment was represented in each replication.

Apparatus. The apparatus was a trio of parallel alleys, each 2.44 m. long. The 2 outside alleys were black and the middle alley was white, thereby allowing spatiality of stimulus presentation as a nonrelevant cue on choice trials. On forced trials, the gray start box was positioned *directly* in front of the appropriate black or white alley and the adjacent alleys were blocked from *S*'s view. The free-choice trials, however, involved placing the start box in such a position that *S* could view both a black and a white alley. Thus, assurances were made so that *S* could view both discriminanda only in the free-choice setting. The apparatus and the start-box arrangement are described in detail by Logan (1960). Photocells were located 10 cm. from the start door, after the first 1.22 m., and directly before the food cup.

Grid floor inserts completely covering .61 m. of the alley and through which shock could be delivered were placed in each of the 3 alleys directly preceding the final .61 m. of the runway. A speaker connected to a tone generator and amplifier, located outside the apparatus, was positioned beneath the grid floor inserts. The start door opened vertically by a spring when released by a solenoid. Goal-box doors lowered manually enclosing the final .61 m. of the alley. Reward consisted of 45-mg. Noyes pellets delivered by Davis feeders.

Shock was delivered by 120-v. ac passing through a variac into a step-up transformer with 120-kΩ resistance in series with *S*. The grid floor consisted of .6-cm. stainless steel rods .3 cm. apart. The shock stimulus was 60 v. at .2-sec. duration, a value used frequently in the relevant literature (cf. Fowler & Wischner, 1969). The 1,000-Hz., 60-db. tone was presented at .2 sec.

Procedure. Pretraining began 1 wk. prior to the beginning of experimentation when *S*s were handled and placed on 23-hr. food deprivation. The *S*s then received 5 days of exploration, goal-box placements, and magazine training in the 3 alleys.

Brightness-discrimination training commenced with the introduction of differential instrumental conditioning. The *S* received 9 pellets in the S+ alley, black for half of the *S*s in each group and white for the remaining *S*s, and 1 pellet reward in the other (negative stimulus, S−) alley. Each *S* received a total of 8 trials/day for 20 days. For *S*s in one set of conditions (forced-free), the first 4 trials of each 8-trial block were forced according to one of the following rotated sequences: + + − −, − − + +, + − − +, − + + − (Logan, 1969). Trials 5 and 6 were free-choice trials and were randomly switched so that over a block of 8 choice trials, the positive alley appeared an equal number of times on the left and the right. Trials 7 and 8 were then forced opposite to those chosen on the free-choice trials (Logan, 1969) The *S*s in the other set of conditions (forced) received only differential conditioning trials in each 8-trial block. The first 4 trials were sequenced as above and the last 4 trials were opposite to the first trials' sequence.

A trial began by placing *S* into the start box and

releasing the start door. When broken, the first photobeam measured starting times on forced trials and choice times on the free trials. When the second photobeam halfway down the alley was broken, *S* received either a shock or a tone, if appropriate. Thus, for example, a shock–right *S* received a shock only when in the S+ alley. A shock–both or tone–both *S*, however, was presented with the appropriate cue on half of the trials in each alley, thereby equating the total number of stimulus presentations. These *S*s received the appropriate stimulus on one positive and one negative trial of the first 4 trials, randomly sequenced from day to day, and then on the opposite positive and negative trials of the second 4 trials of the day. The *S*s were run in squads of 4, providing an intertrial interval of 3–4 min.

Experimental design. A 2 × 2 × 3 factorial, plus 2 control groups, was the experimental design employed. The variables manipulated were type of stimulus (tone or shock), presentation of the trials (forced–free or forced), and alley of stimulus presentation (S+, S−, or S±). The 2 control groups received no stimulus, one group was given forced–free trials and the other group was given only forced trials.

Results

Since all *S*s received 4 initial differential conditioning trials each day, 2 in the positive alley and 2 in the negative alley, those trials formed the primary basis of comparison. The start speeds served as the major dependent variable, in part as a function of the data gen[illegible] in the setting and in part on theor[illegible] [illegible]ounds.

The shock was administered [illegible] middle of the alley. The data dem[illegible]te increased reductions in alley sp[illegible] as the shocked *S*s neared the shock lo[illegible]. These data are consistent with the hy[illegible]sized approach–avoidance gradients [illegible] Miller, 1944), i.e., the avoidance gradie[illegible] [illegible]mes increasingly steep, relative to the [illegible]ach gradients, as *S* nears the shock loca[illegible]. As a result, the *alley* speeds were con[illegible]ded by the presence of shock within th[illegible]ley, making comparisons between shock [illegible]ditions and between shock and no[illegible]ock conditions based on alley speeds diffi[illegible]lt, at best.

The *goal* speeds were confounded because shock served as an intense motivation[illegible]l variable (Spence, 1956) and shocked *S*s ran into the goal compartment unusually fast following presentation of the aversive stimulus. The start speeds were the least confounded measure and could better reflect differential performance of *S*s without the additional and confounding roles of shock, i.e., its aversive and motivation[illegible] capacities. Finally, since the start speed of *S*s with the black stimulus as the S[illegible]

Note. Abbreviations: F = forced trials, FF = forced–free trials.

did not differ with their respective counterbalanced *Ss* with the white stimulus as the S+, those subgroups were combined for the subsequent analyses.

Absolute start speeds. The start speeds to S+ and S− were averaged and appear in tabular form (Tables 1–3). These data suggest that only in the shock groups did the forced–free procedure produce superior differential performance relative to the forced condition. Two analyses of variance of the S+ and S− start speeds over all trials, with all groups included, yielded significant values for both alleys, F (13, 154) = 2.25, $p < .05$, and F (13, 154) = 7.59, $p < .01$, respectively.

A posteriori comparisons (Scheffé method) indicated that the forced–free trained shock–wrong *Ss* ran more slowly in the S− alley than the other *Ss*. The other forced–free *Ss* receiving shock in the S− alley (shock–both) ran slower in that alley than the nonshocked *Ss*, with the notable exception of *Ss* with an informative tone stimulus at that locus, i.e., tone-wrong. Therefore, shock in the presence of the negative stimulus had a significant inhibiting effect, with respect to start speeds, in the S−

Note. Abbreviations: F = forced trials, FF = forced–free trials.

alley. Subsequent comparisons of the groups' performance in the S+ alley indicated no 2 groups differed. One may note that there was the suggestion of differences; however, the error term was sufficiently large to yield no statistically reliable differences.

Relative start speeds. Because shocked *Ss* ran slower than nonshocked *Ss*, relative start speeds to the 2 discriminanda are more appropriate than the absolute speeds for statistical comparisons of discrimination performance. Two relative measures were employed. One such measure (Goldstein & Spence, 1963) is simply the difference between the S+ and S− start speeds. These difference scores are plotted in 2-day blocks in Figure 1. A 2 × 4 factorial analysis of variance was performed on the difference scores of the shock and no-stimulus groups (Figure 1A–1D) with type of training (forced–free or forced), and alley of stimulus presentation (S+, S−, *S*±, or neither S±), as the main factors. The results indicated that both training and stimulus variables significantly influenced responding, F (1, 88) = 31.13, $p < .01$, and F (3, 88) = 47.49, $p < .01$. A posteriori comparisons indicated that each shock group trained under a forced–free procedure yielded greater differences between S+ and S− speeds than its respective shock group receiving only forced trials. Also, shock–wrong groups learned the discrimination more rapidly than their comparably trained shock–right, shock–both, and no-stimulus groups, which did not differ.

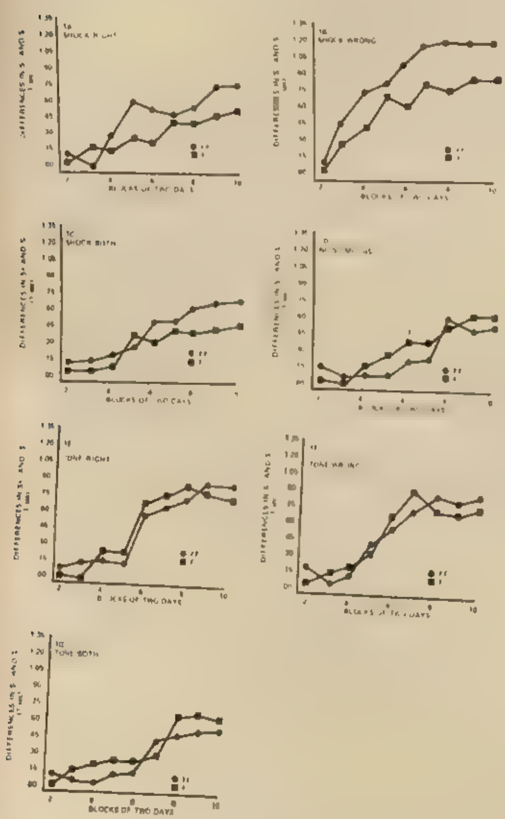

FIGURE 1. The difference between start speeds on the differential conditioning trials in the positive (S+) and negative (S−) alleys. (Each stimulus condition is plotted with its respective forced–free and forced groups.)

A separate 2×4 factorial analysis with the same factors was performed on the data of the tone and no-stimulus groups. As suggested in Figure 1D–1G, the different stimulus presentation procedures had no statistically reliable effect upon the various groups' performance, F (1, 88) < 1. However, the alley of stimulus presentation variable exerted significant effects upon discrimination efficiency, F (3, 88) = 121.01, $p < .01$. A posteriori analyses showed that the performance of tone groups with information (tone-wrong and tone right) was superior to the groups lacking an added informative cue (tone-both and no stimulus).

Thus, the start speeds indicate that interspersing free-choice trials into differential conditioning training produced greater differences between S+ and S− responding only for Ss presented with an aversive stimulus. Furthermore, a redundant, informative stimulus, either tone or shock, enhanced differential responding relative to a no-stimulus control condition.

Correct response measure of speeds—within stimulus conditions. A second way of measuring differential performance, which may be less affected by absolute levels, is the method suggested by Grice (1966). Successive blocks of differential conditioning trials (8 trials in the present experiment) were ranked from fastest to slowest and

ed with respect to the U statistic. rrect response was defined as S running aster in the S+ alley than in the alley. The percentage of correct re-ises for the different stimulus groups is tted in Figure 2. Again the figure gests that the shocked groups differ with spect to number of correct responses on he discrimination under the 2 types of training. A 2 × 4 factorial analysis on percentage of correct responses by the shock groups and the no-stimulus controls (Figure 2A–2D) revealed both type of training and stimulus presentation to be significant variables, F (1, 88) = 24.19, $p < .01$, and F (3, 88) = 38.33, $p < .01$. A posteriori comparisons indicated that each forced–free shock group made more correct responses than its respective forced shock group. Also the shock–wrong groups performed more efficiently than the comparably trained shock–right, shock–both, and no-stimulus groups. Finally, the shock–right and shock–both *S*s made similar numbers of correct responses and both were superior to the similarly trained, forced–free no-stimulus *S*s.

Next, a 2 × 4 factorial analysis was applied to the percentage of correct responses by the tone and no-stimulus *S*s. As suggested in Figure 2D–2G, alley of stimulus presentation yielded a significant value, F (3, 88) = 28.70, $p < .01$, which subsequent a posteriori analyses revealed to be a function of the information groups (tone–right and tone–wrong) making more correct responses than the noninformation groups. In contrast to the speed differences scores, the type of training was also a significant factor, F (1, 88) = 7.38, $p < .01$. However, a posteriori comparisons indicated that there were no differences between forced–free trained *S*s and their comparable but forced *S*s.

Therefore the graphical evidence that the type of training was a significant variable only for the shock groups and alley of stimulus presentation was a significant factor for both shock and nonshock conditions was confirmed statistically with both difference scores and the measure of correct responding.

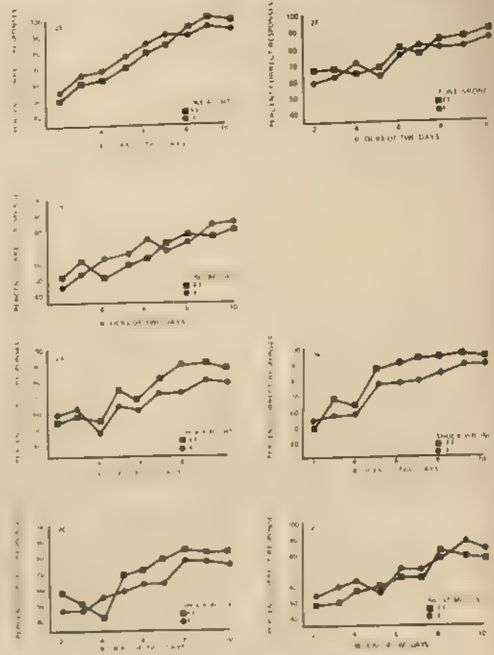

FIGURE 2. The percentage of correct responses on the first 4 differential conditioning trials in blocks of 2 days (see text for explanation). (Each stimulus presentation group is shown in relation to its respective training condition, either forced-free or forced.)

Correct response measure of speeds—between stimulus conditions. Since comparisons of shock, tone, and no-stimulus groups with comparable stimulus presentations were of interest, the correct response measure was employed. Three 2 × 3 analyses of variance with days as a repeated factor were performed with a major interest in the Stimulus Presentation × Days interaction. The assumption was that a significant interaction would suggest different learning rates by the *S*s, a finding relevant to a number of predictions.

Analysis of correct responses of the shock–right, tone–right, and no-stimulus control *S*s yielded significant differences between the various stimulus conditions, F (2, 66) = 17.38, $p < .01$. The Days × Stimulus interaction was also statistically reliable, F (16, 528) = 4.25, $p < .01$. Subsequent a posterior comparisons between the groups indicated that tone–right *S*s trained under both procedures and forced–free trained shock–right *S*s performed more

efficiently than no-stimulus and forced shock–right *S*s. Thus one may conclude that a stimulus in the correct alley facilitates learning the discrimination, with respect to fewer errors and faster rates of learning. However, when shock is used as the cue, this conclusion is valid only if *S*s are allowed free as well as forced trials.

A 2 × 3 factorial analysis was then performed, again with days as a repeated factor, for *S*s with the informative stimulus in the *S*– alley and no-stimulus *S*s. The results indicated that both the stimulus variable and the Days × Stimulus interaction yielded statistically reliable results, $F\ (2, 66) = 48.20$, $p < .01$, and $F\ (16, 528) = 6.40$, $p < .01$. A posteriori analyses between the groups indicated that shock–wrong groups were statistically superior to tone–wrong groups which, in turn, were more efficient than no-stimulus groups. Therefore, shock in the incorrect alley greatly hastened learning the discrimination, and a tone stimulus at that locus produced facilitation relative to the no-information control groups.

A final 2 × 3 factorial analysis with days as the repeated measure was performed on the correct responses of the noninformative groups (shock–both, tone–both, and no stimulus). Although no overall statistical differences were found between the various groups, $F\ (2, 66) < 1$, the Stimulus × Days interaction was a significant factor, $F\ (16, 528) = 2.25$, $p < .01$. A posteriori comparisons between the various conditions revealed that shock–both *S*s trained under the forced–free procedure made

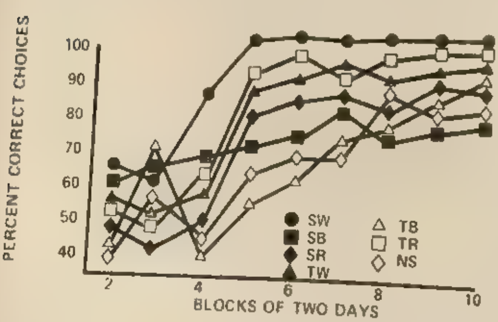

FIGURE 3. The percentage of correct choices on the free-choice trials blocked over 2 days for the forced–free groups.

significantly more correct respon· · than the other noninformative groups. There-fore these data suggest that an u· ·liable aversive stimulus enhanced discri· ·ation performance if *S*s were allowed fre· · well as forced trials.

The general conclusion of the dire· · comparisons of shocked *S*s with thei· ·one-stimulus counterparts and no-stimul· control *S*s indicates that shock in the in· ·rect alley and in both alleys improve· the differential conditioning preformance · ·er tone–wrong and tone–both trainin· ·e-spectively. This generalization is ·n-sonant with the data only insofar as ·he training of the shocked *S*s allows for f· ·e-choice trials. Finally, shock in the cor· ·t alley does *not* improve performance rela to tone–right training, though both to· right and shock–right facilitated perfor· ance relative to no stimulus.

Choice trials. The results of the choic· measure are plotted in Figure 3 alongside the results of the differential conditioning trials. The figure suggests similar ordering of the groups with respect to percentage of correct choices and percentage of correc· responses, with the possible exception tha the shock–right and shock–both perform· ance appears somewhat poorer on the fre· choice trials.

An analysis of variance on the percentag· of correct choices yielded a significant valu·, $F\ (6, 77) = 26.03$, $p < .01$. Subsequent a posteriori analyses indicated that the shoc· wrong group made significantly more correct choices than the other groups. Also, the 2 information groups (tone–right and tone–wrong) performed more efficiently than the no-stimulus control *S*s. Finally, the shock–right and shock–both, tone–both, and no-stimulus groups performed comparably on the free-choice trials.

Summary. Most of the results of the present study are clear and highly reliable. First, interspersing some free-choice trials into a predominantly differential conditioning procedure facilitated discrimination performance, but only for those conditions involving an aversive event. This generalization may be restricted to the relatively simple black–white discrimination

employed in the present investigation, but it is noteworthy. Second, providing an informative, albeit redundant cue in the negative alley facilitated discriminative behavior, and more so if that cue was aversive. Providing an informative, redundant cue in the positive alley was facilitative in the case of the neutral, tone stimulus. However, with respect to the aversive, shock stimulus in the S+ alley, only with one measure, percentage of faster speeds in S+ than in S−, were the effects positive. There was no difference either in raw speed differences or choice behavior. Finally, a noninformative cue produced improved discrimination performance, at least in one measure, but only if that cue was noxious.

Discussion

The results suggest that the role of punishment in differential instrumental conditioning is complex. There is extensive evidence in the data to support the notion that shock in a relatively simple discrimination setting can serve a variety of functions, e.g., as (*a*) an aversive stimulus, (*b*) an informative stimulus, (*c*) a secondary reinforcer, and (*d*) an alerting stimulus.

Consider first the aversiveness or negative incentive value of punishment. Logan (1969) has presented data which suggest that an animal is choosing continuously over time to determine the *net* incentive motivation value associated with an alternative, including not only the parameters of reward, but also the parameters of punishment. Thus, an animal weighs the negative and the positive incentive properties associated with the various response alternatives and responds on the basis of this net incentive value.

This role was clearly evident in several aspects of the present data. The shocked *S*s generally ran more slowly than their nonshocked counterparts. Furthermore, the S− speeds of *S*s receiving the aversive stimulus in the negative alley were reduced relative to the S− performance of *S*s shocked in the positive alley. Also, differential performance developed more rapidly for shock–wrong *S*s, i.e., *S*s with the greater difference in net incentive between the 2 response alternatives, than for any other condition. Finally, a shock stimulus in the positive alley was not as beneficial as a neutral, tone stimulus, suggesting that the differential in incentive between the alternatives was thereby reduced for the shock–right *S*s. Accordingly, this study, including differential conditioning, substantiates the earlier studies (e.g., Fowler & Wischner, 1965) employing simultaneous discrimination learning paradigms in indicating that one of the roles of shock is to contribute negative incentive selectively to the alternative in which it is presented.

A second hypothesized role of shock is its distinctive stimulus or information value, more specifically its secondary reinforcing value in the shock–right procedure. The present data are also generally consistent with this interpretation. The finding that an informative tone facilitated discrimination performance is strong evidence that a redundant, predictive cue is beneficial. An informative shock, as a distinctive stimulus, certainly could have served the same function. Also, that tone–wrong *S*s were as slow in the S− alley as shocked *S*s, with the exception of the shock–wrong condition, is further evidence of the cue value of a stimulus at that locus. Finally, the fact that, at least in one measure, the shock–right procedure was superior to the no-stimulus procedure further attests to this role, in spite of the negative incentive properties of the shock.

Interest then centers on whether there is yet a third role of shock in discrimination learning. Several authors (Muenzinger, 1934; Tolman, 1948) have proposed that shock serves an alerting function in making the animal more sensitive to the stimuli in the experimental setting. The unique contribution of the present study is employing differential conditioning to examine the properties of shock. The data of most interest, therefore, are the speeds on the differential conditioning trials. When the start speeds were transformed to a measure of correct responding, i.e., faster speeds in the positive than in the negative alley, to provide for comparisons of shocked and nonshocked *S*s, the data were highly supportive of an alerting role of aversive stimulation.

The finding that providing shocked *S*s free-choice trials facilitated differential responding, while not aiding the nonshocked *S*s, is consistent with a general alerting interpretation. Muenzinger et al. (1938) contend that shock produces increased amounts of VTE resulting in more efficient discrimination performance. Reducing the opportunity to VTE and comparing the stimuli by giving only single presentations of the stimuli should retard discrimination efficacy. A specific effects analysis, e.g., distinctive stimulus properties (Fowler &

Wischner, 1969), would make no such differential predictions with respect to training procedures. The present data, implicating a comparison of stimuli consequence of shock, support an alerting role of punishment such as that conceptualized by Muenzinger et al.

An important prediction from an alerting analysis is that shock, by virtue of its sensitizing effects, facilitates learning rates relative to comparably trained but nonshocked animals. This prediction was upheld by the data of shock–wrong and shock–both *S*s who had been given free-choice trials, for those *S*s learned the discrimination more rapidly than the similarly trained tone–wrong and tone–both groups. However, a shock or tone stimulus in the correct alley produced comparable learning rates. One may contend that specific effects, i.e., inhibition as a function of aversiveness, of the shock contributed to the shock–wrong facilitation and the lack of facilitation in the shock-right condition relative to their respective tone groups. As a result the shock–both findings take on even greater importance. Providing a nonspecific stimulus, i.e., not associated reliably with either the positive or negative alternative, hastens the learning rates, but only if that stimulus was noxious. Thus, these data also implicate a general alerting role of punishment in discrimination learning.

Of several theoretical formulations of a general effect of aversive stimulation, none appear entirely satisfactory. Tolman (1948) mentioned, but only briefly, that shock produces "looking around" by the animal to see what it was that had hit him. Muenzinger (1934; Muenzinger et al., 1938) proposed an alerting concept, but one which is totally dependent upon VTE behavior. Although the present results implicate a comparison factor, other investigators (e.g., Farlie, 1937; Wischner, 1947), and the present *E* through informal observation, found no reliable relationship between VTE and discrimination efficacy. A more realistic proposal is that the anticipation of shock slows the animal (Logan & Wagner, 1965) allowing it to vacillate at the choice point. This vacillation need not be overt, as is VTE but could be a changing covert perceptual orientation (Spence, 1936) which has an effect similar to that proposed earlier for VTE (Muenzinger et al., 1938), i.e., *S*'s increased sensitivity to the discriminanda.

In conclusion, the novel contribution of the present study involves examining the function of shock in a simple discrimination setting—differential instrumental conditioning. Analysis of the individual response tendencies to each stimulus, a measure not available in the simultaneous discrimination paradigm, indicated that shock serves an aversive role which reduces response strength to the punished alternative. Furthermore, examination of the behavior of animals with an informative, but neutral tone stimulus, a comparison not made previously, indicated that such a stimulus enhances discrimination performance. The implication is clear that the shock, as a distinctive stimulus, is serving a similar function. Finally, a comparison of simultaneous and single presentations of the stimuli, again not attempted previously, suggested a general alerting role of shock. Thus, the present experiment added several unique conditions to the usual shock–right paradigm and substantiated the earlier speculations that shock can serve a variety of roles in discrimination learning.

MEANINGFULNESS, PERCEPTUAL GROUPING, AND ORGANIZATION IN RECOGNITION MEMORY[1]

HENRY C. ELLIS,[2] FREDERICK J. PARENTE, AND E. CHANDLER SHUMATE

University of New Mexico

Two experiments examined the role of meaningfulness (*m*), perceptual grouping, and organizational factors in recognition memory of consonant-vowel–consonant (CVC) trigram stimuli. Experiment I demonstrated that recognition memory of trigram doublets of the integrated form CVC-CVC is a direct function of the *m* value of the stimuli. When the same [illegible] *m* doublets were fragmented by physically separating the letters according to grouping rules, thus disturbing the initial unitary perceptual organization of the stimuli, the effects of *m* were eliminated. The second experiment demonstrated that the fragmented high *m* stimuli operated as if they [illegible] low-*m* stimuli in an associative learning task; their recognition was facilitated by training in which the stimuli were associated with representative [illegible] providing evidence for response-dependent stimulus encoding. In general, contextual variables such as verbal labels are increasingly important in enabling the encoding of stimuli that are low in meaningfulness, perceptual unity, or other indexes of codability.

The fractionated vs. integrated nature of stimuli is thought to be related to the ease with which they can be placed in memory. Highly integrated stimuli (e.g., stimuli high in meaningfulness, *m*) may be encoded quite rapidly as they are processed as a single unit, whereas fractionated stimuli (e.g., low-*m* stimuli) are encoded more slowly because the encoding consists of more than 1 component (Shepard, 1963). This particular account of the underlying dimensions of *m* bears a strong resemblance to Miller's (1956) concept of "chunking," wherein units that may be integrated into larger chunks (and therefore fewer discrete ones) are more easily processed. In a similar vein, variations in stimulus *m* may produce corresponding demands upon *S*'s memory load, with the *m* value of stimuli being negatively correlated with memory load (Ellis, 1973). If low-*m* stimuli are regarded as more difficult to process because of their fragmentary, unintegrated nature, it should be possible to alter the *m* value of a unitary or high-*m* stimulus, and thus the ease with which it can be encoded as a unit, by varying the perceptual grouping of a sequence of letters normally perceived and encoded as a unit.

The primary purpose of the present experiments is threefold: (*a*) to demonstrate a positive relationship between stimulus *m* and recognition, (*b*) to determine if the effect of stimulus *m* depends upon the degree of integration of the stimuli, or the ease with which they may be perceptually grouped into a unit, and (*c*) to determine if fragmented high-*m* stimuli operate as low-*m* stimuli in the sense that their recognition is, to a great extent, dependent upon contextual cues present during associative training.

The first experiment examined the effect of stimulus *m* on recognition memory with both integrated and fractionated letter sequences. The recognition memory test provides a sensitive measure of the extent to which *S* has encoded the stimulus in a unitary fashion, because the test requires recognition of a target stimulus compared with a distractor item high in formal similarity to the target item. Although some studies (e.g., Ellis & Shumate, 1973) have demonstrated a positive relationship between stimulus *m* and recognition, negative relationships have also been reported (e.g., McNulty, 1965); moreover, the rela-

[1] This research was supported by National Science Foundation Grant GB-27413X to the first author, and by a National Defense Education Act graduate fellowship to the third author.

tionship also known to depend upon the scale of m [illegible]. Ellis, Muller, & Tosti, 1966). Thus, it was deemed necessary to establish this relationship for purposes of obtaining baseline data. The experimental question was: Does the effect of stimulus m (as defined by conventional norms) on recognition memory depend upon the integrated vs. fractionated character of the letter sequences?

The second experiment provided evidence for the view that fractionated high-m stimuli do, in fact, behave as low-m stimuli in an associative learning task. Several experiments have shown that recognition memory for visual form stimuli (Ellis & Daniel, 1971, Experiments I & II) and verbal materials (Ellis & Shumate, 1973; Ellis & Tatum, 1973) may be enhanced as a result of associative training. When stimuli are paired with "representative" verbal responses (labels), the stimuli are subsequently better recognized than when they are paired with "nonrepresentative" responses or are simply observed without associative training. Ellis (1973) has proposed that the facilitative effect upon recognition memory for stimuli paired with representative responses is dependent upon the initial codability of the stimuli, with relatively greater facilitative effects occurring with less codable stimuli. This proposition asserts that ambiguous, unintegrated, or complex stimuli are more dependent upon contextual events for their encoding than are familiar, integrated, or simple stimuli. Ellis and Shumate (1973), viewing m in terms of codability, with low-m stimuli being less codable than high-m stimuli, found that recognition memory facilitation for trigram stimuli paired with representative responses was dependent upon the m value of the stimuli, with reliable facilitation in recognition performance occurring with low-m stimuli, whereas no differences obtained with high-m stimuli.

The question of interest in the second experiment was whether associative training with the degraded high-m stimuli, using representative response terms, would produce an effect upon stimulus recognition memory similar to the findings obtained with low-m stimuli by Ellis and Shumate (1973). The experimental question was: Can a response which is representative of the stimulus provide, during associative training, cues that enable S to organize or integrate nominally fragmented stimuli? The assumption was that a representative response can effectively instruct S in how to organize or integrate a fragmented stimulus so that it is more readily encoded as a unit.

Experiment I

Method

Experimental design. The *Ss* were 40 undergraduate student volunteers from the University of New Mexico. Each S received 4 study–recognition test trials to learn a mixed list of 12 trigram doublets containing 3 levels of m. The *Ss* were randomly assigned to 1 of 2 list conditions in which the doublets were either "integrated," i.e., appeared as intact trigram pairs, or "fractionated" (degraded), i.e., broken up into particular letter groupings other than the original trigrams. The *Ss* assigned to the fractionated stimulus condition were tested 1 wk. later than those in the integrated stimulus condition, although both were drawn from the same population of *Ss*.

Stimuli. The integrated items were trigram doublets constructed by combining 2 trigrams selected from the Archer (1960) norms. For example, the trigrams BAN and COW were combined to form the doublet BANCOW. Doublets rather than trigrams were used in order to require S to encode more information and to allow for construction of different distractors on each recognition trial in accord with a single construction rule. Four doublets of each of the m levels (high, moderate, and low) were used, with average association values of 100%, 56%, and 12%, respectively. The doublets used were BANCOW, RUMWIG, CUPNET, DENGIT, PUZWEK, [illegible], [illegible], CIMBUX, NEJWOQ, TIJFRQ, YIWFEP, and MOJZEX, and were typed in [illegible]

The same doublets were used in the fractionated condition, in which each appeared as perceptual groupings of 1 or more letters. (If it is true that high-m stimuli are more easily encoded and hence better recognized than low-m stimuli because they can be more readily processed as a unit, then fractionation of the doublets should make the high- and moderate-m items more difficult to encode. Accordingly, recognition performance differences typically associated with variations in stimulus m should be either reduced or eliminated.) The 6 letters of each doublet were grouped according to 1 of 4 fractionation rules that simply regulated the number of letters in each group. For example, the 4 high-m doublets, BANCOW, CUPNET, RUMWIG, and DENGIT, were presented in the following forms, each

adhering to a different fractionation rule: BA NC OW, C UPN ET, R UMWI G, and DE NGI T. The moderate- and low-*m* doublets were also fractionated according to the same grouping rules, and each stimulus maintained the same form or grouping rule throughout the study–test sequence.

Procedure. All *Ss* were given 4 study–test trials to learn either list. The order of items was randomly varied on each trial. The doublets were presented consecutively on a Stowe memory drum at a 1-sec. presentation rate. The *Ss* were instructed to remember as many items as possible. After viewing all 12 items, *Ss* were given a 2-alternative forced choice recognition test in which they were shown each of the *old* items, singly, paired with a highly similar distraction item. Distractors were formally similar to the *old* items, with a distractor consisting of a 1-letter substitution of 1 of the 4 middle letters of the original doublet. A vowel was replaced by a vowel and a consonant was replaced by a consonant.

For *Ss* learning integrated items, the *old* item BANCOW appeared, for example, with the distractor BENCOW on one trial, BAZCOW on another, and so on. As *Ss* were presented with each *old–new* pair, they were instructed to underline the stimulus they had seen during the study trial. A different distractor item was used on each of the 4 trials, and the right–left position of the pairs was randomly varied on each trial. For *Ss* learning fractionated items, the same construction rules were used; however, the distractor items were fractionated according to the same grouping structure as the *old* items. For example, BA NC OW was paired with BE NC OW on 1 trial, BA ZC OW on another, and so on.

Results

Figure 1 is a plot of the proportion of correct recognitions of the trigram doublets for the conditions of the experiment. The left panel shows recognition performance curves for the integrated stimuli, and the right panel portrays the results for the fractionated stimuli. The left panel clearly shows the differential effects of *m* upon recognition learning, with high-*m* stimuli producing superior recognition performance, followed by moderate-*m* stimuli and low-*m* stimuli showing the poorest performance. In contrast, the right panel indicates that *m* produces no differential effect upon recognition when the items are fractionated. The mean proportions of correct recognitions of the integrated items, averaged over 4 trials for the high-, moderate-, and low-*m* conditions, were .86, .81, and .70, respectively. In contrast, for the fractionated items, the recognition scores averaged .62, .60, and .60, respectively. The interaction between *m* and stimulus grouping was reliable, $F\ (2, 76) = 4.51$, $p < .025$, which is the finding of principal interest. The effects of grouping (integrated vs. fractionated stimuli) was also highly reliable, $F\ (1, 38) = 41.03$, $p < .001$, and the overall effect of *m* was reliable, $F\ (2, 76) = 6.86$, $p < .01$. Separate analyses of the effect of *m* for the integrated stimuli yielded a reliable difference, $F\ (2, 38) = 11.14$, $p < .001$, whereas the effect of *m* with fractionated stimuli was not significant, $F\ (2, 38) < 1$, $p > .05$.

The figure shows the obvious effect of trials, $F\ (3, 114) = 85.00$, $p < .01$. The *Ss* learned the integrated items faster than the fractionated items, as reflected in the Trials × Grouping interaction, $F\ (3, 114) = 87.50$, $p < .01$, and the $m \times$ Trials interaction was reliable, $F\ (6, 228) = 5.00$, $p < .01$.

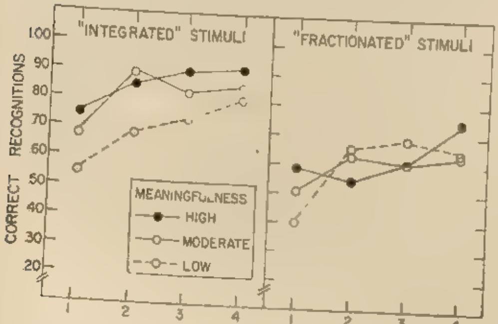

FIGURE 1. Recognition learning as a function of stimulus meaningfulness with integrated and fractionated trigrams.

EXPERIMENT II

The results of Experiment I provide direct support for the view that the effect of stimulus *m* on recognition performance is dependent upon the structural properties of the trigram doublets. High-*m* stimuli, when fragmented or grouped so that their unitary property is less readily detected, are recognized at approximately the same level as moderate- and low-*m* fragmented stimuli. It follows that if the high-*m* stimuli have indeed become functionally equivalent to low-*m* stimuli, then they should operate as low-*m* stimuli under other experimental conditions. Since it is known that low-*m*

stimuli are most susceptible to response-dependent encoding (Ellis, 1973; Ellis & Shumate, 1973), it would follow that degraded or fractionated high-*m* stimuli should show a similar effect. Ellis and Shumate (1973) have shown that the formation of an association between stimuli and responses can affect the recognizability of stimuli, and that this facilitative effect is evident only with low-*m* stimuli. This effect occurs with responses that are representative of the stimuli, but not with unrepresentative responses. In general, the conditions under which contextual cues aid in stimulus encoding are those with stimuli that are initially difficult to encode (Ellis, 1973). Therefore, it would follow that if fragmented high-*m* stimuli are paired with representative responses during associative training, such training would facilitate stimulus encoding compared with associative training in which the responses were nonrepresentative.

Method

The *Ss* were 70 undergraduate student volunteers from the University of New Mexico. Twenty *Ss* were assigned at random to each of 2 experimental conditions and 15 *Ss* to each of the remaining 2 conditions. All *Ss* were given 8 paired-associate (PA) trials to learn a list of 8 stimulus–response pairs. The stimulus terms were either integrated or fragmented high-*m* trigram doublets and were identical for both conditions except, of course, for the groupings. (The *Ss* assigned to the integrated stimulus conditions were tested 12 wk. later than those in the fractionated stimulus conditions. Nevertheless, *Ss* in both conditions were drawn from the same population of introductory psychology classes. Furthermore, the integrated stimulus conditions represent a replication of the immediate recognition condition of Ellis and Shumate (1973), and since quite comparable recognition results were obtained in that and the present experiment, the comparability of the groups is reasonably assured.) For 1 group of *Ss* the doublets were each paired with a representative response, and for the other group each doublet was paired with a nonrepresentative response. Each stimulus was exposed for a 4-sec. period consisting of a 2-sec. anticipation interval and a 2-sec. simultaneous presentation with the response. The intertrial interval was 4 sec. The *Ss* were tested individually, and the materials were presented via a Stowe memory drum. The response terms were common words, equated for frequency of occurrence between groups in accordance with the Thorndike–Lorge (1944) norms. Response representativeness (or belongingness) was determined by agreement among 6 judges as to whether or not a particular word selected "resembled" its stimulus mate. Judges were asked to rate each response as being representative in the sense of being descriptive, suggestive, or relevant to the stimulus. A nonrepresentative response was judged as bearing little, if any, relationship to its corresponding stimulus mate. These procedures are comparable to those employed by Ellis (1968) in studies of visual shape recognition. In the case of verbal stimuli, these operations basically mean selection of response terms that are formally and/or acoustically similar to the stimuli. Although the defining operations of response representativeness clearly imply a multidimensional concept, all that is necessary for the present experimental purposes is the selection of 2 classes of pairs for associative learning: 1 set of pairs that is relatively easy to associate and 1 that is relatively difficult. An example of pair types is M EDVA N associated with MAIDEN as a representative response, and with UMPIRE as a nonrepresentative response.

After *Ss* received PA training they were given a forced choice stimulus recognition test that required them to select 1 of 5 highly similar stimuli as being the *old* item seen during training. The 5 stimuli (the *old* item and 4 distractors) were typed in a single row on a white 5 × 8 in. card. The distractors were constructed as outlined in Experiment I and were grouped in the same manner as the *old* item with which they appeared.

Results

The primary data were the scores from the recognition test. Response representativeness exerted no effect on stimulus recognition with integrated high-*m* stimuli; mean recognition scores following either type of associative training were identical (.83). In contrast, with fractionated high-*m* stimuli, the recognition scores for the representative and nonrepresentative response conditions were .79 and .44, respectively. The expected Stimulus Structure × Response Representativeness interaction was present, F (1, 66) = 14.75, $p < .01$. Clearly, context effects during associative training are present, but only with the fractionated stimuli, which operate as poorly integrated units and thus benefit from contextual responses which effectively instruct *S* in how to unitize or organize the letter sequences.

The effects of stimulus structure (integrated vs. fractionated) and response representativeness were both reliable, F (1,

66) = 27.66, $p < .001$, and F (1, 66) = 12.60, $p < .001$, respectively.

Discussion

Experiment I provided baseline data demonstrating the effects of *m* on recognition memory for trigram doublet stimuli. The results indicated a positive and systematic relationship between the recognition of a stimulus and its *m* value. This finding is consistent with those of Ellis and Shumate (1973) using similar stimuli and with experiments using random shape stimuli (e.g., Ellis, 1968; Price & Slive, 1970). The first experiment provided empirical support for Shepard's (1963) hypothesis that *m* is highly correlated with the degree of analyzability of the stimuli. This hypothesis contends that low-*m* stimuli are likely to be analyzed into separate components, i.e., they are likely to be processed or encoded into more than 1 unit, whereas high-*m* stimuli are likely to be processed in a more unitary manner. Fractionation of high- and moderate-*m* stimuli produced a substantial reduction in recognition performance.

A straightforward interpretation of these findings is that the fragmented high-*m* stimuli have become, in effect, functional low-*m* stimuli. This position is reasonable if the view that the underlying dimension of *m* is the degree to which a verbal stimulus may be encoded as a unit is adopted. Fractionating a stimulus, particularly a high-*m* stimulus, makes it more difficult for *S* to encode that stimulus as a unit and therefore effectively reduces its *m* value. Relating these findings to Miller's (1956) chunking notions, a further interpretation of the results seems quite simple and straightforward. High-*m* stimuli may be regarded as involving fewer chunks of information than low-*m* stimuli, even though the number of letters in each stimulus class is identical. Thus, *S*s learning low-*m* stimuli attempt to place more units or chunks of information into memory than *S*s learning high-*m* lists. This differential memory loading, attributable to varying levels of *m*, is reflected in recognition memory performance, wi[illegible] learn[illegible] high-*m* material performing [illegible] than *S*s learning low-*m* material. [illegible], wh[illegible] high-*m* stimuli are fractionat[illegible] numbe[illegible] of chunks of information req[illegible] for h[illegible] learning to take place is inc[illegible] hereb[illegible] increasing *S*'s memory load[illegible] consi[illegible] quently lowering recognition [illegible]

The purpose of Experiment [illegible] to demonstrate that when a high-[illegible] stimul[illegible] is fractionated it does, in fact, [illegible] a low-*m* stimulus under different [illegible] mental conditions. The positive r[illegible] of the experiment suggest, again, th[illegible] the *m* effect is a function of the integ[illegible] fractionated nature of the stimulus. The consequence of fractionating a high-*m* stimulus is to make it more difficult for *S* to perceive and encode that stimulus as a unit. The function of a representative [illegible] sponse may be seen as one of reinteg[illegible] or organizing the stimulus by sugge[illegible] a possible unitary encoding. More ge[illegible] ally, this experiment suggests that [illegible] cedures that enable or encourage *S* to encode stimuli as units may be regarded as increasing the *m* value of that stimulus. By the same token, procedures th[illegible] courage *S*s to encode stimuli in [illegible] of their components may be seen as decreasing the *m* value of that stimulus. Finally, the results of Experiment II support the generalization that contextual events (such as responses) are most likely to affect the encoding of stimuli that are initially difficult to encode.

CONNOTATIVE EVALUATION AND CONCRETENESS IN SHORT-TERM MEMORY[1]

GEORGE D. GOEDEL[2]

State University of New York College at Geneseo

Encoding processes were investigated using the release from proactive inhibition (PI) paradigm with word triads derived from the factorial manipulation of evaluative connotation (E) and concreteness (C). The recall data indicated significant PI buildup for all E×C conditions with less PI for concrete vs. abstract triads while no differential PI for good vs. bad triads. Proactive inhibition release was found for shifts on either E or C, or both, compared to their appropriate no-shift controls only when postshift items were abstract. For postshift abstract items, simultaneous shifts on E and C produced better recall than shifts on C only, but not better than shifts on E only. The data were evaluated in terms of a dual encoding mechanism for concrete word items and Paivio and Begg's offsetting interference hypothesis.

Considerable evidence has accumulated over the last decade for proactive inhibition (PI) and PI release with successive trials on a Brown-Peterson (Brown, 1958; Peterson & Peterson, 1959) short-term memory (STM) task. The use of PI release as a potential indicator of how information is encoded in STM has perhaps received its most cogent explication in a recent review by Wickens (1970). He proposed that words are encoded into memory along a number of dimensions or attributes and identified a large number of these dimensions, via PI release, gauging their relative dominance in terms of percentage of release.

The concern of the present study was with 2 such dimensions, connotative evaluation (E) as defined by the semantic differential (Osgood, Suci, & Tannenbaum, 1957) and concreteness (C). The fact that the former is employed as an encoding class in STM has been fairly well established (Turvey, 1968; Wickens & Clark, 1968). Evidence suggesting such encoding for the latter, however, has been lacking. Wickens and Engle (1970) [illegible] differential encoding by means of PI [illegible] for words differing on this dimension [illegible] although their results suggested differential interference for abstract vs. concrete word triads, their negative release results raised doubts concerning differential encoding.

The differential interference interpretation proposed by these authors, in terms of greater semantic overlap for abstract items, was recently challenged by Paivio and Begg (1971) who failed to find support for such an interpretation when interference was defined in terms of interitem associative relatedness. Paivio and Begg proposed instead that imagery is a source of resistance to interference among concrete items based on the assumption that high-imagery words are encoded differently from abstract words. According to dual encoding theory (Paivio, 1971), the availability of imagery as an alternative or additional code for concrete items might enhance their recall relative to abstract items by offsetting the interference effects of a verbal code, the only code available for abstract items. Unfortunately, Paivio and Begg did not include a shift in triad class in their study in which release could be evaluated. Thus, the Wickens and Engle (1970) failure to obtain release with this dimension has remained a question.

---

[1] This article is based in part on a dissertation submitted to Southern Illinois University at Carbondale in partial fulfillment of the requirements for the PhD degree. The author is indebted to Robert C. Radtke for his direction and guidance as chairman of the dissertation committee.

The present study sought to explore further the phenomena of PI buildup over trials and PI release with concrete and abstract word triads by also including the connotative evaluative dimension. By using words rated on both E and C, shifts on one or both of these dimensions could be evaluated. The inclusion of the E dimension would provide a reliable encoding class under either an abstract or concrete triad condition and shifts on this dimension should result in PI release regardless of C level. This dimension was also chosen since it was not controlled in the Wickens and Engle (1970) study and there was the possibility that it may have been confounded somewhat with their imagery-concreteness manipulation. This possibility arose from the fact that these authors selected word stimuli from the Paivio, Yuille, and Madigan (1968) norms allowing imagery and C ratings to covary since they tend to correlate highly (.83). However, since Paivio et al. noted that words which differ on these 2 scales with imagery ratings being higher than C ratings tended to be words with "strong emotional or evaluative connotations," failure to control for E may have resulted in some confounding.

The present study also investigated the release phenomenon as a function of the number of prior PI buildup trials, since shifts in triad class occurred after either 4 or 8 prior interference trials. This variable was included since it was thought that perhaps recall performance had not reached asymptotic level prior to a shift in class in the Wickens and Engle study where only 3 preshift trials were given. This assumption appeared reasonable in the light of an earlier study by Wickens, Born, and Allen (1963) where significant release from PI was obtained with a shift from number–number–number to consonant–consonant–consonant trigrams relative to a consonant–consonant–consonant control after 9 prior PI buildup trials but not after 3 or 6 such trials.

Method

Design and materials. The design included 4 basic triad classifications derived from the 2 × 2 factorial combination of E (good vs. bad) and C (concrete vs. abstract). There were 4 shift conditions: shifts on E only, C only, both dimensions simultaneously, or no shifts on either dimension. Within each of the shift conditions there were 8 groups, with 2 groups representing each of the 4 triad classifications. One of these 2 groups received a shift after a block of 4 prior PI buildup trials, while the other group received a shift after 8 such trials. This design defined the 32 groups that were required to investigate the PI buildup and release phenomena.

In order to obtain the words needed for each of the 4 triad conditions, 2 groups of 30 introductory social psychology *Ss* rated words on each of 2 scales, good–bad and concrete–abstract, since available norms contained few words with ratings on both these dimensions. A total of 160 nouns were selected from available norms of C and E for rating by these *Ss*. Each *S* received a 40-page booklet containing 80 of these critical words (20 from each E × C combination as subjectively determined by *E*) plus 80 filler words. Each of the 2 groups of 30 *Ss* received a different set of 80 critical words but the same 80 filler words. Each page of the booklet contained 4 words with 2 7-point rating scales, concrete–abstract and good–bad, below each word with the former scale always located above the latter for each of the words rated. The booklets were constructed such that 2 critical and 2 filler words appeared in random order on each page. Five random page orders were employed yielding 5 different ordered booklets for each of the 2 sets of words.

Means and standard deviations were calculated from the ratings for each of the critical words and were used to select and place them into one of the following classes: good concrete (GC), bad concrete (BC), good–abstract (GA), and bad abstract (BA). Good was arbitrarily defined as a mean rating ranging 1.00–3.20 on the good–bad scale while bad had ratings ranging 4.80–7.00. Similarly, concrete was defined as mean ratings ranging 1.00–3.20 on the concrete–abstract scale, while abstract words had mean ratings ranging 4.80–7.00. A total of 27 nouns were chosen from each E × C combination. The overall mean ratings of the nouns chosen for each condition were as follows: for GC, 2.09 and 1.63; GA, 2.13 and 5.72; BC, 5.73 and 1.86; and BA, 5.81 and 5.41. The 27 nouns selected for each triad condition were also matched as closely as possible across classes for Thorndike–Lorge (1944) frequency. In constructing word triads, care was taken such that, within a triad there (*a*) was minimum interitem association, (*b*) was variable frequency, (*c*) were different initial letters and variable number of syllables for the words, and (*d*) were variable activity and potency connotative values, as subjectively determined by *E*.

Subjects and procedure. Eight *Ss* were tested in each of 32 groups giving a total of 256 *Ss*. All were undergraduate volunteers enrolled during the summer term at Southern Illinois University at Carbondale. For each of the 32 conditions there

were 2 random presentation orders of the triads since complete counterbalancing would have required too many groups. For each of the conditions, these orders were determined in the following manner. First, 2 random orders for each of the no-shift control groups were defined. The shifted groups then received the same triads in the same order as their preshift controls on preshift trials and the same triads in the same order as their postshift controls on the trial of shift in materials and trials following. Within each condition, 4 *Ss* received each random-order replication. The *Ss* were tested individually and randomly assigned to the 32 groups in the order they came into the lab, with the restriction that the $n + 1$ *S* was not assigned to a group until the nth *S* had been assigned to every other group.

Each word was mounted on a 2 × 2 in. slide and rear-projected by means of a Kodak Carousel projector. After *S* was seated in the experimental room, the typical instructions for the Brown–Peterson (Brown, 1958, Peterson & Peterson, 1959) STM paradigm were read. Two 20-sec. practice periods of backward counting by 3s were then given prior to the start of the experiment to familiarize *S* with the counting task. A trial began with a 2-sec. presentation of an asterisk as a signal that the first word of a triad was about to be presented. Following this signal, the 3 words of the triad were presented individually for 1 sec. each with a projector change time of about .75 sec. The *S* was instructed to read each word aloud as it was presented. Following the last word of the triad, a 3-digit number (from a random-number table) appeared on the screen and remained for a duration of 20 sec. During this time, *S* was required to count backwards aloud from this number by 3s paced by a metronome set at a 1-sec. rate. After 20 sec. of counting, a question mark appeared on the screen and remained for 8 sec. as a signal to *S* to orally recall the words of the previously shown triad. Immediately after the recall interval, an asterisk once again appeared on the screen, signaling the beginning of the next trial. All *Ss* received a total of 9 trials in this manner. The presentation sequence was co[...] by a Gerbrands tape timer.

C × T	3	7.15*
E × C × T	3	2.94
Error (*MS*)	756	(.59)

* $p < .01$.

RESULTS

Proactive inhibition buildup. The initial analysis was a 2 × 2 × 4 mixed design, with C (concrete or abstract), E (good or bad), and trials (1–4) as the repeated factor. The results of this analysis are given in Table 1.

In terms of percentage of recall, abstract triads (59.3%) were significantly lower overall than concrete (68.3%), and performance, summed over all conditions, dropped from Trial 1 through Trial 4: 90%, 63%, 55%, and 48%, respectively. The significant C × Trials interaction indicated differential performance across trials for the abstract and concrete triad groups with percentage of recall dropping more rapidly, to a lower final level, for the former. Simple main effect trials analyses for each triad condition indicated significant PI buildup across trials for all 4 triad conditions with the following *F* ratios: GC, $F(3, 756) = 25.54$, GA, $F(3, 756) = 31.53$, BC, $F(3, 756) = 30.63$, and BA, $F(3, 756) = 53.56$, all $ps < .01$. Further analysis

dicated that the groups did not differ .. each other on Trial 1. The percent ill scores for the 4 triad conditions over first 8 trials for those groups not re- ing a shift in triad class on Trial 5 can seen in Figure 1.

)ne additional analysis, a 2^3 between-*S*s .ign, which compared the performance the 4 E × C triad conditions on Trial 4 roups that received 4 PI buildup trials) ith that on Trial 8 (groups that received PI buildup trials) failed to yield any significant effects at the .01 level and thus indicated no further PI buildup with ad- itional trials.

Proactive inhibition release. A 2^5 be- tween-*S*s design was used to examine the release phenomenon. This design included the 2 levels of E and C prior to a shift in triad class (preshift), 2 levels of each dimension following a shift (postshift), and trial of shift (5 or 9). Since no main effect of trial of shift or any interactions with this factor were significant (all *F* ratios < 1), the data were collapsed over this factor and are given in Table 2.

This analysis yielded 4 significant effects: a postshift C main effect, $F(1, 224) = 20.84$, a Preshift × Postshift C interaction, $F(1, 224) = 11.60$, a Preshift × Postshift E interaction, $F(1, 224) = 35.45$, and a triple Preshift × Postshift E × Postshift C interaction, $F(1, 224) = 11.60$, all $ps < .01$, with *MS* error = .74. The 2 double interactions can best be seen by reference to Tables 3 and 4.

TABLE 2

Percentage of Recall for Each Pre- × Postshift Manipulation

Preshift condition	Postshift condition: Good, Concrete	Good, Abstract	Bad, Concrete	Bad, Abstract
Good				
Concrete	58.3	60.3	79.3	87.7
Abstract	75.0	31.3	77.0	62.7
M	66.7	45.8	78.1	75.2
Bad				
Concrete	73.0	66.7	62.7	41.3
Abstract	79.3	75.0	77.0	25.0
M	76.1	70.8	69.8	33.1

TABLE 3

Percentage of Recall for Preshift × Postshift Concreteness: Proactive Inhibition Release

Preshift	Postshift: Concrete	Postshift: Abstract
Concrete	68.3	64.0
Abstract	77.1	48.0
M total	72.7	56.1

From Table 3 it can be seen that recall was substantially better with concrete than abstract postshift triads and that shifted groups exhibited better recall than their appropriate nonshifted controls. Simple main effect analyses comparing the groups shifted with their appropriate nonshifted controls revealed that only the groups shifted from concrete to abstract triads recalled significantly more than their post-shift controls, $F(1, 224) = 9.50$, $p < .01$, while groups shifted from abstract to concrete did not differ from their nonshifted controls. Therefore, significant C shifts were restricted to postshift abstract triads.

Reference to Table 4, the Preshift × Postshift E interaction, also shows superior performance for the shifted E groups compared to appropriate nonshifted controls. However, this interaction also interacted with postshift C as seen by referring to Table 2 where percent recall scores are given collapsed over preshift C. Analysis of the simple Preshift × Postshift E interaction at each level of postshift C indicated a significant interaction effect only when postshift triads were abstract, $F(1, 224) = 43.24$, $p < .01$. It should

TABLE 4

Percentage of Recall for Preshift × Postshift Evaluation: Proactive Inhibition Release

Preshift	Postshift: Good	Postshift: Bad
Good	56.2	76.7
Bad	73.2	51.5
M total	64.7	74.1

perhaps be noted that the direction of the interaction for the postshift concrete triads, although not significant, also indicated better recall for the groups shifted on E than those not so shifted. Furthermore, inspection of the Preshift × Postshift E interactions indicated similar differences between shifted groups and their respective postshift controls, i.e., relatively symmetrical shift effects regardless of direction (from good to bad or vice versa). Consonant with these observations, simple main effect analyses comparing groups shifted on E with appropriate postshift control groups indicated significant shift effects from bad to good and good to bad with postshift abstract triads, $F(1, 224) = 12.16$, and $F(1, 224) = 33.74$, respectively, both $ps < .01$, but no significant effects in either direction with postshift concrete triads.

Another way to evaluate the triad shift data was to partition the groups into 4 different shift conditions (no shift, shift on E only, C only, and both E and C) and analyze recall on the 4 E × C postshift triad types with the additional factor of trial of shift (5 or 9). In this analysis, the effects of shifts on a particular dimension were isolated from shifts on other dimensions, whereas in the previous analysis, the effects of shifts on one dimension were averaged over shifts and no shifts on the other dimension.

Neither postshift E, trial of shift, nor any interactions involving these factors were significant. Significant effects were obtained for shift condition, $F(3, 224) = 16.63$, postshift C, $F(1, 224) = 20.84$,

TABLE 5

PERCENTAGE OF RECALL FOR THE VARIOUS SHIFT CONDITIONS UNDER BOTH LEVELS OF POSTSHIFT CONCRETENESS

Shift condition	Postshift concreteness	
	Concrete	Abstract
No shift	60.0	28.0
Concreteness (C) only	76.0	51.0
Evaluation (E) only	76.0	68.7
Both C and E	79.3	77.0

Note. Data averaged over Trials 5 and 9.

and the Shift × Postshift C interaction, $F(3, 224) = 4.16$, all $ps < .01$, with MS error $= .74$. Mean percentage of recall for this analysis, collapsed over postshift E and trial of shift, is given in Table 5.

Simple shift conditions main effect analyses under each level of postshift C indicated a significant effect only under postshift abstract, $F(3, 224) = 18.27$, $p < .01$, consistent with the previous analyses. Pair-wise comparisons of the various shift conditions under postshift abstract yielded significant differences between each of the shifted conditions and the no shift condition as well as a significant difference between the double (E-C) shift condition and the C only condition with an overall .05 alpha level.

Discussion

With regard to the question of differential PI buildup, the data clearly show differences in such buildup as a function of C but not E. Previous studies have tended to suggest no differential buildup for words on either end of the evaluative dimension (Turvey, 1968; Wickens & Clark, 1968) and this is confirmed by the results of the present study. The finding of greater PI accumulation over trials for abstract triads compared to concrete triads is likewise consistent with available evidence (Paivio & Begg, 1971; Wickens & Engle, 1970). In general, a facilitative effect of concreteness and or imagery has been demonstrated in a variety of verbal learning situations where this dimension has been manipulated (Paivio, 1971) and thus, would not be unexpected here.

If PI release is defined in terms of the difference in recall performance between a group shifted on one or more dimensions and its postshift control, then reliable release was demonstrated for shifts on both E and C as indicated by their respective Preshift × Postshift interactions.

Reliable release for shifts on E simply replicates the results of previous studies (Turvey, 1968; Wickens & Clark, 1968) and was not unexpected. One finding of interest in this regard however, was that shifts on E interacted with postshift C such that the difference between shifted and appropriate nonshifted controls was significant only under the postshift abstract condition. If, as Wickens and Engle (1970) implied, abstract

and concrete words are not encoded differently and represent a dimension of relative unimportance in an STM experiment, then release should have obtained with shifts on E irrespective of the level of C. If instead, imaginal encoding offsets the interference effects of a verbal code (such as connotative evaluation), as has been suggested by Paivio and Begg (1971), then little release would be expected with shifts on E when the words are highly concrete contrasted with a large release with shifts on E when the words are highly abstract. The results of the present study are entirely consistent with this latter prediction.

Furthermore, the present study also indicated reliable release for shifts on C (for concrete to abstract triad shifts) which Wickens and Engle (1970) failed to obtain. Several reasons for such a discrepancy might be given. The present study contained a number of procedural differences from that of Wickens and Engle such as the amount of time given for recall (6 vs. 8 sec.), requesting *S*s to recall triad items in serial order of presentation vs. free-recall instructions, and the presentation of all 3 items of the triad at one time for 3 sec. vs. presentation of each item of the triad separately for 1 sec. each. One might argue that this last difference is crucial in the sense that more total time was available in the present experiment than in the Wickens and Engle study, to encode the words of a triad prior to the distractor task (due to projector change time), thus allowing more time for image formation. However, as Paivio (1971) has pointed out, evidence would seem to suggest that image latency to single words is in the order of .6 sec. which would tend to minimize the importance of such a distinction.

A major difference between the studies was the control for E. This may be important in the sense that a reliable dimension (E) was available in the present experiment for encoding regardless of the C manipulation, whereas in the Wickens and Engle (1970) experiment, no consistent dimension other than C was available.

When one considers the very nature of the C dimension, it becomes apparent that the situation with respect to shifts on this dimension is considerably more complex than shifts on other dimensions. Concrete and abstract words may be considered alike in that both may be encoded verbally and, as such, there should be no differential encoding. However, concrete words provide for an additional encoding mechanism, imagery. This dual encoding possibility for concrete words does not exist for other encoding dimensions investigated by Wickens (1970) and his colleagues and makes this dimension unique in that respect. Thus, when one shifts from abstract to concrete words, an additional encoding mechanism is made available to the one employed preshift. Performance on such a shift might reasonably be expected to improve relative to that preshift but not necessarily be significantly different from a control which always had the opportunity to employ a dual encoding mechanism. A shift from concrete to abstract (dual encoding to single encoding mechanism) should result in a decline in performance relative to that preshift due to the loss of an encoding mechanism. Performance on such a shift might not be expected to differ from an abstract control unless one of the following prevailed. First, if substantial interference buildup occurred for images in addition to such buildup for a verbal code, then a shift from concrete to abstract items would eliminate imaginal interference resulting in PI release relative to an abstract control. Such a hypothesis seems unlikely since it would also predict greater PI buildup over trials for concrete vs. abstract triads, a situation which has been repeatedly shown to be the reverse.

The second possibility, which would predict a difference in performance in favor of a group shifted from concrete to abstract relative to an abstract control, as well as superior performance preshift for concrete items, involves Paivio and Begg's (1971) offsetting interference hypothesis. If the availability of an imaginal code preshift offsets the interference effects generated by a verbal code, then a shift from a dual encoding mechanism to a single encoding mechanism (verbal) should result in a performance decrement from that demonstrated preshift but to a level somewhat above an abstract control where interference buildup along a verbal code would have been great. This latter possibility would predict an empirical demonstration of PI release. The C shift results of the present study would appear consistent with this offsetting interference hypothesis and Paivio's (1971) dual encoding theory for concrete words.

SHORT REPORTS

PRONUNCIATION AND APPARENT FREQUENCY IN A BETWEEN-SUBJECTS DESIGN [1]

LARRY WILDER,[2] JOEL R. LEVIN, ELIZABETH S. GHATALA, AND SANDRA McNABB

University of Wisconsin—Madison

College students were administered a list of middle frequency words, in which individual words were presented 1–6 times. Half of the *S*s pronounced the list, while the other half remained silent. On a subsequent frequency judgment task, pronunciation *S*s failed to differ significantly from silent *S*s on mean judgments of items presented only once; however, there were differences on these items as indexed by variability and mean total correct measures. Analysis of judgments of *zero* items (not seen on the study list) indicated differences between silent and pronunciation *S*s on all 3 measures, while the pronunciation effects tended to be eliminated on the items presented more than once. These results were contrasted with previous findings and explained within a frequency theory perspective.

Situational frequency, as described by Ekstrand, Wallace, and Underwood (1966), has been shown to be a principal attribute in verbal discrimination learning (VDL) and recognition memory. In VDL, situational frequency is in part a function of rehearsal of the correct response, which leads to an increased frequency differential between the correct and incorrect members in a pair. In recognition memory, frequency of exposure during the learning trial is a significant factor affecting performance (Underwood & Freund, 1970).

Spoken rehearsal has been found to be superior to control (i.e., silent) performance in VDL (Wilder, 1971). Frequency theory can account for this finding if it is assumed that pronouncing during rehearsal increases the situational frequency differential between the correct and incorrect item. Hopkins, Boylan, and Lincoln (1972) tested this assumption in a frequency judgment task. In one experiment, they found no difference in mean frequency judgments between *S*s who pronounced all words on the study trial and *S*s who did not pronounce (Experiment 3). However, when this manipulation was made within *S*s, pronunciation did increase apparent frequency (Experiment 4). That is, when *S*s pronounced some words but not others in the same list, they judged the pronounced words to have a higher frequency of occurrence. These results led the authors to conclude that pronunciation influenced (increased) apparent frequency only "if *S* has also had experience with silently studied items in the same experimental context [Hopkins et al., 1972, p. 112]," and at the same time permitted a frequency explanation of the facilitative effect of pronouncing the correct response in VDL.

However, Underwood (personal communication, November 1971) has justly pointed out that an *absolute* mean increase in the situational frequency associated with the "correct" response in VDL, or with previously seen items in recognition memory, is not the only way in which an increased frequency differential can occur. For example, if pronunciation *S*s exhibit lower variability than silent *S*s on list items with the *same* situational frequency, then an equivalent increased frequency differential among items with *different* situational frequencies would be the result. Thus, while Hopkins et al. (1972) found no mean differences in an independent groups design, it is possible that pronunciation increases item discriminability by reducing the variance of mean frequency judgments for items of the same situational frequency. In other words, while apparent frequency units may not be added as a function of pronouncing the items on a study list, more consistent frequency estimates of items with the same situational frequency would be expected to produce the same net result in VDL and recognition memory tasks.

Accordingly, the present experiment was intended to assess the effects of pronunciation on frequency judgment variability in a between-*S*s design. In addition, a measure found to be correlated with, but more sensitive than, within-*S* variability—total number of correct frequency judgments (Ghatala & Levin, in press)—was considered. The experiment itself was similar to Hopkins et al. (1972), Experiment 3; however, in addition to just study list items, a number of filler items were presented during the second (test) list. It was predicted that if pronunciation decreases variability on items previously seen, this would result in increased discriminability between these items and items not presented, as in recognition memory.

Method. A total of 42 upper division University of Wisconsin communication arts students participated in the experiment for partial course credit.

The stimuli consisted of 2 lists of middle-frequency (10–20 on the general Thorndike–Lorge, 1944, list) 2-syllable nouns. The study list contained 90 words. Fifty of the words were presented once; 25 were presented twice; 10 were presented 3 times; 3 were presented 4 times; one was presented 5 times; and one was presented 6 times. In all, there were 153 presentations. The list was divided so that each word occurred equally often in equal divisions of the list (e.g., for the one word that occurred 6 times, the list was divided into sixths). The second list was the test list, which included all of the 90 words from the study list plus 10 additional words that had not been presented on the study list.

The first list was presented on a memory drum at a 2-sec. rate. Two groups of *S*s were used. A pronouncing group was told:

> This is an experiment on word memory. You will be shown a long list of words. Some words will occur once, while others will occur twice on up to six times. Your task is to look at each word carefully and pronounce it. The list is too long to actually count and remember all of the words, so just try to get an impression of the number of times each word has occurred.

A silent group was given the same instructions, but they were told only to look at each word carefully. A test list was presented once on a memory drum at a 3.5-sec. rate to both groups. All of the *S*s reported verbally how many times they had seen the word before. They were told that they could report *zero* for any item that they had not seen previously.

Results. A summary of *S*s' frequency judgment performance on the *one* and *zero* items, as well as the average number of correct frequency judgments (out of 100), is presented in Table 1 with the corresponding statistics based on pronunciation–control differences. Since the predictions derived from frequency theory were all quite explicit (i.e., pronunciation should result in larger means and smaller variability on *one* items, in both smaller means and variability on *zero* items, and in a greater number of correct frequency judgments), all comparisons made were directional and thus the significance probabilities reported in Table 1 are 1-tailed.

TABLE 1

SUMMARY MEASURES AND ONE-TAILED SIGNIFICANCE PROBABILITIES CORRESPONDING TO PRONUNCIATION–CONTROL DIFFERENCES

Measure	Control	Pronunciation	t (40)	p
		One items		
M	1.090	.947	−1.46	—[a]
Variance	.603	.456	−1.84	<.05
		Zero items		
M	.348	.115	−3.63	<.001
Variance	.326	.152	−2.37	<.025
		All items		
Total correct	45.19	55.10	3.18	<.005

[a] Wrong direction.

Mean apparent frequencies were computed for each *S* by averaging his frequency judgments on the 50 *one* items. The same was done for each *S* on the 10 *zero* items. The mean in Table 1, therefore, represents the average mean across *S*s in the same condition. As may be seen, the difference between the pronunciation and control conditions for mean judgments of *one* items was in the wrong direction and consequently nonsignificant, which corresponds to the Hopkins et al. (1972) result. Mean judgments for *zero* items did result in significant differences between the 2 conditions, however.

Within-*S* variances were obtained on *one* and *zero* items by computing each *S*'s mean squared deviation (about his apparent frequency mean). The entries in Table 1 represent the average of these within-*S* variances within each condition. Pronunciation resulted in lower average within-*S* variances, particularly on the *zero* items.

The total correct measure was computed by counting the total number of times *S*'s frequency judgment corresponded exactly to the appropriate actual frequency. It can be seen that pronunciation *S*s averaged about 10 more correct responses than did control *S*s (this effect was found to hold for both *one* and *zero* items when analyzed separately).

Analysis of means and variances of items presented more than once detected only one other statistically significant pronunciation–control difference: lower within-*S* variances for pronunciation *S*s on the *four* items, t (40) = 2.12, p < .05.

Discussion. These results are consistent with those of Hopkins et al. (1972) in that there was no significant difference between pronunciation and silent *S*s on mean frequency judgments. However, going beyond mean frequency judgments, significant differences between silent and spoken performance were detected in a between-*S*s design. There was less variability within *S*s, as well as a greater mean total correct, for *S*s who pronounced the *one* items. Further, the prediction that *S*s who pronounced the items on the study list were better able to discriminate items they had not seen before was confirmed.

From these results it would appear that Hopkins et al. (1972) were premature in discounting the effects of pronunciation in a between-*S*s design, and that frequency theory can account for these results if it is assumed that reduced variability contributes to improved frequency discriminations. Also, it is not surprising that these effects tend to be eliminated when items are presented more than once, since Ekstrand et al. (1966, p. 575) have suggested, according to Weber's law, that adding frequency

its to items with greater situational frequency should be less noticeable.

COGNITIVE PROCESSING OF LINEAR ORDERINGS[1]

KARL W. SCHOLZ[2]
Indiana University

GEORGE R. POTTS
Dartmouth College

This study attempted to discriminate between 2 theories about strategies Ss use when trying to remember a linear ordering. Rating-scale theory argues that *Ss* represent the items to be learned as points along an imaginary spatial continuum. End-term anchoring theory suggests that serial orderings are learned from the end points inward. A scaling analysis of proportions correct suggested that neither theory alone is sufficient. The Ss apparently represented ordering information along 2 dimensions, the first representing the distance between items on the imaginary continuum and the second representing the distance of the items from the center of the ordering.

In an attempt to clarify the encoding strategies *Ss* use when trying to remember a linear ordering, Potts (1972) had Ss learn a paragraph that presented an ordering of 4 terms along a meaningful dimension. Such a 4-term ordering (A > B > C > D) can be broken into 6 pairs of terms, 3 of which (the "adjacent" pairs, A > B, B > C, and C > D) represent relations between adjacent elements in the ordering and are therefore essential to the establishment of that ordering. The remaining 3 pairs (the "remote" pairs, A > C, B > D, and A > D) are redundant in the sense that they can be deduced from some subset of the adjacent pairs. Potts found that responses to the remote pairs were both faster and more accurate than responses to the adjacent pairs. This was true even when the remote pairs were never presented and thus had to be deduced from the adjacent pairs. These data were shown to be inconsistent with several possible theories regarding the form in which such information is stored. Two theories were proposed that could account for this result.

The first of these theories, an extension of Huttenlocher's (1968) spatial-imagery model, argues that Ss represent the items to be learned as points along an imaginary spatial continuum and will be referred to herein as *rating-scale theory*. In such a model, forgetting is represented by variability in the placement of the items on this scale. The Ss incorrectly identify a particular pair whenever the variability between the 2 terms comprising that pair is sufficiently large to permit the 2 terms to cross each other on the scale. This model would predict proportion correct on a pair to be a monotonic increasing function of the distance between the 2 terms comprising that pair. Since the terms of a remote pair would have to be placed farther apart on the scale than the terms of any adjacent pair necessary to deduce it, the theory would necessarily predict better performance on the remote pairs than on the adjacent pairs.

An alternative explanation of Potts' (1972) result is provided by research (DeSoto & Bosley, 1962; Feigenbaum & Simon, 1962; Wishner, Shipley, & Hurvich, 1957) suggesting that serial lists are learned from the end points inward, with the first and last terms serving as "anchors" for the other terms in the list. If one accepts the argument that there is less variability in the identification of the ordinality of end terms, it follows that performance on the remote pairs should surpass performance on the adjacent pairs since, on the average, the remote pairs contained more end terms than did the adjacent

[1] This work was supported by U. S. Public Health Service Grant MH-16817. The authors wish to thank Henry Halff, Larry Jones, and Janet Walker for their critical appraisal of the manuscript.

pairs. In what follows, this will be referred to as an *end-term anchoring theory*.

A straightforward test of these 2 alternatives would involve examining proportion correct as a function of distance, with number of end terms held constant. If proportion correct still increased as a function of distance under this condition, we would conclude that end-term anchoring was not important. If, on the other hand, holding the number of end terms constant eliminated the effect, the importance of end terms would be affirmed. Unfortunately, with the 4-term orderings employed by Potts (1972), the effects of distance and number of end terms were completely confounded. The present experiment examined proportions correct on 6-term orderings in an attempt to unconfound these 2 factors.

Method

Subjects. The *S*s were 40 Indiana University undergraduates who participated to fulfill a course requirement. Each *S* served in a single 30-min. session.

Apparatus. The experiment was conducted in the Mathematical Psychology Laboratory at Indiana University. Stimuli were presented on an 11-in. Sony video monitor that was controlled by an Applied Digital Data Systems MRD-280 video character generator. True–false responses were obtained using a 2-button response box located immediately below each video monitor. Each button was appropriately labeled with the word *true* or *false*. Stimulus presentation and response collection were controlled by an IBM 1800 process-control computer.

Materials. Stimuli consisted of 9 English paragraphs presented one at a time on the video monitor. Each paragraph represented a linear ordering among 6 items along a unique dimension. The syntax for all 9 paragraphs was identical and presented the intended ordering as 5 pair-wise relations. Several researchers (Clark, 1969; Huttenlocher, 1968; Jones, 1970; G. R. Potts and K. W. Scholz, manuscript in preparation) have shown that differences in the linguistic markedness of certain oppositional adjective pairs affect the speed with which sentences using these adjectives are processed. In order to avoid any unintentional confounding by lexical marking, the 5 relational terms used in each paragraph were identical. In order to reduce variability in the case of paragraph comprehension, the surface structure of each paragraph was held constant. Each of the 9 paragraphs had the structure, "Mary is smarter than Jim, and Jim is smarter than Betty. Betty is smarter than Tom. Tom is smarter than Alice, and Alice is smarter than Bob." If the capital letters A–F are used to represent the 6 items, and the symbol > used to represent the relation, then the surface structure of each paragraph can be represented as "A > B and B > C. C > D. D > E and E > F."

The 6-term orderings used in the present experiment permit the testing of 15 distinct pairs of terms. Each test statement consisted of a single sentence such as "Jim is smarter than Alice." For each true test sentence of the form "A is smarter than B," there was a corresponding false sentence of the form "B is smarter than A" that presented the same 2 terms in reverse order. In this way, a total of 30 statement types was obtained. Each statement type was tested 3 times in a session. The 90 test statements were randomly assigned to the 9 paragraphs with the constraint that 5 true and 5 false statements followed each paragraph.

Procedure. From 1 to 4 *S*s participated in each experimental session. Prior to the beginning of the session, *S*s were given a brief training trial to acquaint them with the apparatus and procedure. This training trial consisted of presenting *S*s a sample paragraph followed by 2 sample test questions which they were required to answer

Following this training trial, the first of the 9 test paragraphs was presented on the viewing screen. The paragraph remained in view for 90 sec or until all *S*s indicated (by a button press) that they could remember the information in the paragraph. The time required to study each paragraph was not specifically recorded, but spot checks revealed that this time rarely exceeded 60 sec. As soon as all *S*s in a session indicated that they were ready, the screen was erased and the first test statement presented. The *S*s were instructed to respond to the statement (by a button press) as quickly as possible. As soon as all *S*s had responded, the test statement was erased, and the next statement was presented after a 1-sec. intertrial interval. The procedure was identical for the 10 test statements following each of the 9 paragraphs.

Results and Discussion

Mean proportions correct for each of the test pairs, averaged over true and false sentences, are presented in Table 1. The entry in each cell represents the proportion correct on the pair made up of those terms indicated by the row and column headings. Each pair can be characterized according to the number of end terms it has (0, 1, [illegible] its step size (1, 2, 3, 4, or 5), where the [illegible] of a pair refers to the number of adja[illegible] necessary to deduce it. Clearly, step size is a monotonic function of the distance separating the terms of the pairs.

A 2-way analysis of variance (step size by true/false) indicated a significant main effect for step size, F (4, 156) = 9.84, $p < .001$, but not for true vs. false, F (1, 39) = 2.98, $p = .09$. Orthogonal polynomial trend analysis revealed a signifi[illegible] linear trend, F (1, 156) = 29.71, $p < .001$, for step size. Higher order trends were not significant. The observation that performance is better for more widely separated items is consistent with Potts' (1972) data and conforms to the predictions of the rating-scale model. However, the average number of end terms included in the test pairs increases monotonically as a function of step size. Thus, the apparent step size effect could also be explained by

the assumption that end terms are more readily accessible.

Similarly, average proportion correct is higher for pairs that include an end term than for pairs that do not, t (39) = 5.04, $p < .001$. Though this effect is consistent with the predictions of the end-term anchoring theory, it is confounded with step size.

In an attempt to distinguish between the 2 models, proportion correct as a function of step size was examined, with number of end terms held constant. First, proportion correct as a function of step size was examined for those test pairs which did not include any end term (i.e., for the subordering BCDE). The mean proportions correct for pairs with Step Sizes 1, 2, and 3 were .713, .758, and .771, respectively. This represents a significant linear trend, F (1, 78) = 3.84, $p = .05$, which accounted for almost all (89%) of the variance between the cell means of the step size variable. Thus, as predicted by the rating-scale theory, even with the number of end terms held constant at zero, proportion correct is still a monotonic increasing function of step size.

Second, proportion correct as a function of step size was examined for those test pairs that included exactly one end term. The mean proportions correct for pairs with Step Sizes 1, 2, 3, and 4 were .771, .850, .858, and .804, respectively. These proportions correct are clearly not a monotonic increasing function of step size. The quadratic trend in this case was highly significant, F (1, 117) = 18.05, $p < .001$, and accounted for almost all (88%) of the variance between the cell means of the step size variable. The linear trend was not significant, F (1, 117) = 2.33, $p = .13$, and accounted for only 11% of the variance.

The extent to which the present data are inconsistent with the predictions of a rating-scale theory can also be seen by examining the exact predictions of such a theory. Let the first through sixth terms in the ordering be represented by the numbers 1 through 6, respectively; let $D(ij)$ represent the spatial distance between the items i and j on the scale; and let $P(ij)$ represent the proportion correct on the pair consisting of the items i and j. The basic prediction of a rating-scale theory is that $P(ij)$ is a monotonic increasing function of $D(ij)$. In other words, for any i, j, m, and n, $P(ij) = P(mn)$ if and only if $D(ij) = D(mn)$, and $P(ij) > P(mn)$ if and only if $D(ij) > D(mn)$.

If one examines the nature of a linear scale, it becomes apparent that $D(ij) > D(mn)$ whenever $i \leq m$ and $j \geq n$. (The only exception is the trivial case where both $i = m$ and $j = n$, and this case can be ignored in the present analysis.) Thus, a rating-scale theory would predict that $P(ij) > P(mn)$ whenever $i \leq m$ and $j \geq n$. Examination of Table 1 indicates that this prediction is completely consistent with the data for those pairs that do not include either end term (i.e., pairs included in the subordering BCDE), but fails among those pairs that do include one of the end terms. Though performance is best on the pair A > F, which is

TABLE 1

Proportions Correct on 15 Test Pairs

Pair	A	B	C	D	E	F
A	—					
B	.771	—				
C	.858	.738	—			
D	.842	.763	.713	—		
E	.783	.771	.754	.688	—	
F	.871	.825	.875	.842	.771	—

the most distant, performance is better on the pairs A > C and A > D than on the pair A > E; and performance is better on the pair A > C than on the pair A > D. Similarly, performance is better on the pairs D > F and C > F than on the pair B > F.

Thus, it appears that although a rating-scale theory can account for the proportions correct on pairs relating to the inner terms (BCDE), its predictions are incorrect with respect to the proportions correct on pairs which contain one of the end terms. In order to clarify the nature of the discrepancies, a multidimensional scaling analysis was performed on the proportions correct. In doing this, the scaling assumption that proportion correct is a monotonic increasing function of distance was accepted, but the dimensionality of the resulting cognitive space was viewed as an empirical question. The scaling solutions that follow were obtained using TORSCA, a FORTRAN IV program, described by Young and Torgerson (1967).

The rating-scale theory predicts that the cognitive space is unidimensional, since it argues that *Ss* place the terms along a line. Thus, the unidimensional scaling solution based on proportions correct should reflect the true spatial distances between the items, and thus would have to result in those items being ordered correctly on the scale. To the extent that the unidimensional solution does not correspond well to the actual ordering of the terms, it would indicate that the unidimensional rating scale is not an accurate representation of the way *Ss* store or access the ordering.

The unidimensional solution is shown in the top frame of Figure 1. It is clear that this solution does not accurately represent the true ordering of the terms. The stress values for the 1-, 2-, and 3-dimensional solutions were .274, .027, and .001, respectively. The poorness of the unidimensional fit relative to the 2-dimensional fit is readily apparent. In order to investigate the possibility that the 1-dimensional solution shown in Figure 1 was the consequence of entrapment in a local minimum, stress was estimated for the ABCDEF ordering, assuming both equal spacing and spacing that emphasized the remoteness of the end terms. Using the numerical method described by Kruskal

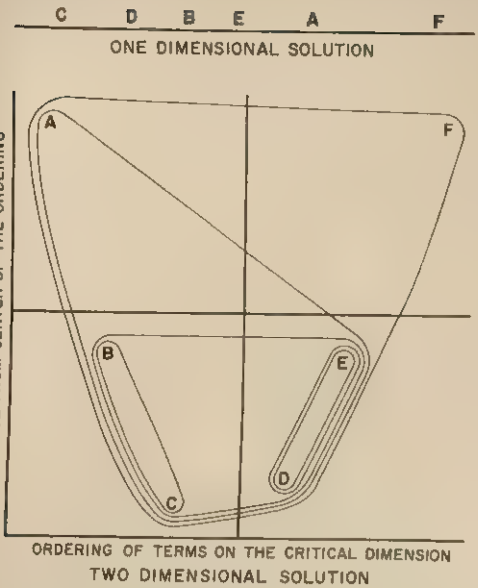

FIGURE 1. The 1-dimensional (upper frame) and 2-dimensional (lower frame) scaling solutions for proportions correct.

(1964), we discovered no set of distances that would yield a stress of less than .2.

The problem with the unidimensional solution becomes apparent when one examines the best 2-dimensional solution, shown in the bottom frame of Figure 1. A pair of easily interpretable orthogonal axes is included in the figure. The projection of points onto one of these axes gives the actual linear ordering of the terms on the critical dimension; the projection on the other axis gives the distance of each item from the center of the ordering. It is clear that the end terms are very different from the inner terms (BDCE) of the ordering on both dimensions. On one dimension, however, these end terms are the items which are farthest apart; on the other dimension, they are closer to each other than they are to any other item.

The clustering analysis presented along with the 2-dimensional solution was obtained using the diameter method. The result again demonstrates the uniqueness of the end terms relative to the other terms in the ordering. Use of the connectedness method yielded minor differences in the clustering among the inner terms, but showed essentially the same effect.

Our interpretation of the 2-dimensional scaling solution is that one dimension represents the distance between items on an imaginary scale. The ordering of the items along this dimension is consistent with a rating-scale theory. The other dimension represents the distance of the items from the center of the ordering. On this dimension, items more distant from the center of the ordering (hence nearest the ends) are grouped together. The grouping is consistent with the assumption of end-term anchoring theory that end terms are learned best.

The conclusion drawn from the results is that neither a rating-scale theory nor an end-term anchoring theory is adequate in itself as an explanation of how *S*s process linear orderings. The predictions each theory would make about performance were described earlier. The results suggest that the theories be integrated. Apparently, the accuracy of *S*'s attempt to identify the truth or falsity of a test pair is a function of the ease with which the relative position of each item can be identified (as in the rating-scale theory). In addition, position identification is facilitated if the item is an end term in the complete ordering (as in an end-term anchoring theory). These 2 components could reflect either differences in how the information is structured in memory, or differences in the strategies by which the information is retrieved. Further work would be necessary to discriminate these 2 alternatives.[3]

[3] We note that there is a superficial similarity between our task and various psychophysical scaling tasks. Our task was designed to investigate memorial representation and retrieval of linearly ordered meaningful material, and as such we feel that an attempt to relate our findings to existing psychophysical models would be unwarranted and potentially misleading.

B–A LEARNING AS A FUNCTION OF DEGREE OF A–B LEARNING

C. MICHAEL LEVY[1] AND DOROTHY D. NEVILL

University of Florida

Two studies were conducted to examine the backward-learning function. In Experiment I, 5 groups of 20 *S*s each learned an 8-item A–B list where the A and B terms were single alphabetical or numerical symbols. Learning was to a criterion of either 0, 2, 4, 6, or 8 correct anticipations. Subsequently, *S*s were trained to an 8/8 criterion on the B–A list. Experiment II was designed to control for the required temporal delay between A–B and B–A learning in Experiment I. The data revealed a number of similarities between the A–B and B–A functions, but provided no support for the associative symmetry hypothesis or for one of its important variants.

Systematic studies of the acquisition of backward associations are rare. Jantz and Underwood's (1958) study today has only heuristic value due to methodological difficulties resulting from their use of nonsense syllable–adjective pairs. In general, studies using these materials have not addressed adequately the problem of stimulus–response availability. It could be argued that on the completion of forward (A–B) learning an *S* would have learned B and the association between the A and B terms. But since the A term had not been specifically learned as such, and indeed *S* may not have attended to all of the nominal attributes of the A term, it would not be as available as the previously learned B. Several methods have been used to control for availability of stimulus–response terms, including prelearning and use of double-function lists. However, the former method has the possibility of producing interitem connections which could greatly modify subsequent paired-associate learning and the latter results in lower rates of B–A learning than when other types of lists are learned. Consequently, a simpler solution to the problem of the unequal availability of A and B terms is to avoid using highly complex stimuli (e.g., nonsense syllables) and to use instead very simple, highly available items such as single digits or letters of the alphabet (Ekstrand, 1966).

A recent study (Baumeister & Campbell, 1971) attempted to avoid the design problems discussed above by using black and white drawings of highly familiar objects in order to equate their availability as both stimulus and response terms. Baumeister and Campbell observed an orderly relationship between the forward and backward associative functions, although the relationships were not identical for the normal and retarded children studied. In their first experiment, where the focus was the amount of B–A recall as a function of the degree of A–B learning, the number of A–B trials was the principal variable manipulated. In contrast, the proportion of the A–B list correctly anticipated in the present studies was varied in order to examine its influence upon the course of B–A learning.

EXPERIMENT I

Method. The list were composed of 8 single digit and letter pairs selected to maximize item availability. The digits 2–9 were chosen, all of which rank in the upper quartile in association value for the numbers 0–100. The letters used were B, M, S, T, H, D, R, and F, which are among the 9 letters highest in meaningfulness. The materials were presented on a memory drum at a 1:1 rate to minimize intratrial rehearsal and to prevent *S*s from "running through" the A–B sequence during B–A learning (Ekstrand, 1966).

During Stage 1, *S*s engaged in forward anticipation learning. Group 8 learned a list to a criterion of 8 out of 8 correct responses. Subjects in Groups 6, 4, and 2 were taken to criteria of, respectively, 6 out of 8, 4 out of 8, or 2 out of 8 correct responses. Group 0 was not presented with the A–B list, but proceeded directly to Stage 2.

Stage 2 consisted of backward anticipation learning. A 1-min. period intervened between Stages 1 and 2 during which the instructions were given for the second stage. All groups learned the B–A list to a criterion of 1 perfect errorless anticipation.

List order was systematically varied so that half of the *S*s in each group received digits as A terms and letters as B terms, while the reverse contingency was used for the remaining *S*s. Four different orders of items occurred before the lists repeated. There was a 2-sec. interval between each trial.

The *S*s were 105 female undergraduates fulfilling psychology requirements, 20 being randomly assigned to each of the 5 groups. Five *S*s (1 each in Groups 0, 2, and 8, and 2 in Group 4) failed to reach criterion on either the A–B or B–A list within 30 trials and were excused, being replaced by the next arriving *S*s.

Results. In an analysis of total trials to criterion, no main effect for group, $F < 1$, or for order, $F < 1$, was found. It appeared as if the groups learned the lists at the same rates overall and were thus comparable. There was, however, a highly significant difference between the total trials to criterion in Stages 1 and 2, $F(1, 90) = 57.71$, $p < .001$. Since *S*s were required to

[1] Requests for reprints should be sent to C. Michael Levy, Department of Psychology, Psychology Building, University of Florida, Gainesville, Florida 32605.

learn to 1 of 5 possible criteria during A–B learning but to a criterion of 1 errorless trial during backward learning, the average number of trials to reach criterion on A–B was suppressed relative to B–A.

The degree of learning during Stage 1 had a reliable effect on performance during Stage 2, $F(4, 90) = 42.15$, $p < .001$. The mean number of trials required by the major groups to reach criterion in Stages 1 and 2 were, respectively, Group 2, 5.1 and 19.9; Group 4, 7.7 and 18.9; Group 6, 14.0 and 10.8; and Group 8, 17.9 and 7.9; Group 0 required 21.0 trials to learn the materials to 1 errorless trial. The inverse relationship between trials to criterion required for Stages 1 and 2 suggests that some B–A associations were being formed during A–B learning.

The Stage × List Order (letter–numeral vs. numeral–letter) interaction was also significant, $F(1, 90) = 6.3$, $p < .001$. The *S*s given letters as A terms and numerals as B terms performed proportionally better during A–B learning, requiring an average of 7.84 trials to criterion, than their counterparts who were presented numeral–letter combinations, requiring 9.98 trials, and proportionally worse during Stage 2 (16.86 vs. 14.52 trials, respectively). This suggests that the letter–numeral combinations were easier than the reversed pairings, reflecting either greater absolute availability for the numerals than the alphabetical characters or a higher expected value for correct responses due to guessing, since the number of potential items in the pool of single digits is less than the number of potential letters.

Prior to reaching the criterion necessary for a shift to Stage 2, Groups 4, 6, and 8 each passed one or more of the critical criteria. By combining appropriate groups during Stage 1, it was possible to determine the performance on the first postcriterion trial, a determination that was necessary for the evaluation of Trial 1 performance during B–A learning for those proceeding to Stage 2. Thus, for example, the scores of Groups 6 and 8 were averaged on the first trial after the criterion of 4 correct responses was achieved during Stage 1 in order to evaluate the B–A strength of Group 4 on the first B–A anticipation trial during Stage 2. At all comparable points there was a reliable decrement ($p < .01$) in performance averaging 28.6% at Criterion 2, 25.6% at Criterion 4, and 23.8% at Criterion 6 when *S*s were shifted from A–B to B–A learning. When only the anticipations correct on both the criterion trial and first postcriterion trial were examined, the corresponding decreases were 38.7%, 21.4%, and 24.0%. Thus, as Wollen, Allison, and Lowry (1969) have shown, the principle of associative symmetry was neither supported on an individual item-by-item basis nor in the more general case of the average number of items anticipated.

EXPERIMENT II

In Experiment I, a 1-min. delay between the critical trial in Stage 1 and the first trial of Stage 2 was necessary in order to change lists on the me[mory] drum. But the corresponding interval betwee[n the] criterion trial and the first postcriterion tria[l for] the comparison groups continuing in Stage 1 [was] only 2 sec. Additionally, in the previous c[om]parisons, there was a potential bias in favor [of] continuing A–B learning who were not subj[ect to] the loss of set. A second experiment was the[n] designed in which 3 groups were interrupted du[ring] Stage 1 learning after reaching a given criter[ion] and were engaged in conversation for 1 min. [Ac]quisition of Stage 1 was then resumed.

Method. The materials were identical to those used in Experiment I.

The *S*s were 31 female undergraduates ta[ken] from the same pool and during the same acade[mic] quarter as those who served in Experiment [I]. One *S* failed to reach the Stage 1 criterion wi[thin] 30 trials and her data were voided.

Three groups of 10 *S*s each participated [in] Stage 1 until a given criterion of learning [was] reached, after which they were engaged in co[n]versation with *E* for 1 min. Training then resu[med] for Stage 1. Group 4A was interrupted a[fter] making 2 correct responses and proceeded to [a] criterion of 4 out of 8 correct anticipati[ons]. A second delay interval then occurred du[ring] which *E* changed the lists on the memory d[rum] and after which Stage 2 began. The proced[ure] for Group 8A was similar except that a 1-mi[n.] interruption for conversation occurred after each of the first 3 criteria (2, 4, or 6 correct responses) were reached. The group was subsequently trained to a criterion of 1 perfect recitation (and give[n] a final interruption) prior to commencing Stage 2. Groups 4A and 8A learned the B–A list to a criterion of 1 errorless trial. Group 8B was trained to a criterion of 1 errorless trial in Stage 1, and was then interrupted for 1 min. of conversation before receiving 2 additional trials of Stage 1 learning. It received no training on Stage 2.

Results. Prior to determining the effects of the 1-min. interruption, the preinterruption performance of Groups 4A, 8A, and 8B was compar[ed] to Groups 4, 6, and 8 used in Experiment I. [The] 6 groups entered one analysis of variance of the number of trials to reach criteria of 2 and 4 correct anticipations in Stage 1. Groups 6, 8, 8A, and 8B were compared on the number of trials to criteria of 2, 4, and 6 correct anticipations. Data from Groups 8, 8A, and 8B were used in a third analysis of trials to reach 2, 4, 6, and 8 correct anticipations. Inasmuch as the groups main effects fell far short of significance in these analyses (all Fs < 1), the preinterruption A–B performance of the groups in Experiments I and II were pooled for subsequent comparisons.

In order to evaluate the effects of the 1-min. interruption on subsequent A–B and B–A performance, 2 post hoc groups were formed. Forward-interrupted *S*s, composed of Groups 4A, 8A, and 8B, were given 1 or more 1-min. interruptions during A–B learning. Backward-interrupted *S*s, including Groups 4, 6, and 8, had their major interruption immediately prior to B–A learning.

After each learning criterion was attained, the number of correct responses was determined on the first postinterruption trial. Table 1 indicates that there was an inverse relationship between the Stage 1 criterion and postinterruption improvement. The decrement at Criterion 8 and the increment at Criterion 2 in the number of correct anticipations after the interruption were highly reliable, yielding *z*s of 3.67 and 2.98, respectively. When *S*s were shifted to the first trial of Stage 2, their correct anticipations decreased by 25%–30% relative to *S*s who were given a 1-min. interruption before resuming Stage 1 learning. Except at Criterion 4, all of the decrements were statistically reliable.

Table 1 also presents the mean number of anticipations that were correct on both the criterion trial and the first postinterruption trial. Except for the limiting case at Criterion 8, there were fewer correct anticipations in this analysis than in the preceding one. But, as in the previous analysis, the first-trial performance on Stage 2 was significantly inferior to that after a 1-min. interruption for those continuing in Stage 1 in each comparison except Criterion 4.

Discussion. Although the methodologies used in the present study and by Baumeister and Campbell (1971) were quite different, the data are strikingly similar. When *S*s were given highly available materials, a considerable amount of backward learning occurred at each test criterion in forward learning. The A–B and B–A functions were approximately mirror images.

The present data, however, offer strong contraindications for the associative symmetry hypothesis (Asch & Ebenholtz, 1962) and for the revision of this hypothesis proposed by Wollen et al. (1969). If it may be assumed that the 1-min. interruption used in Experiment II controlled for the disruption of set and/or for the opportunities to forget in *S*s shifted to Stage 2, then the associative symmetry hypothesis remains untenable. Regardless of whether the dependent variable was the average number of postcriterion anticipations or the average number of anticipations correct on both criterion and postcriterion trials, performance on the B–A task was poorer than it was at the comparable points in A–B learning.

It is equally important to note that, even with rapid rates of presentation used to minimize the opportunities for backward rehearsal, an appreciable amount of B–A learning occurred during the process of A–B learning. The backward associative strength, after correcting for the effects of the 1-min. interruption, was estimated at 70%–75%

TABLE 1

MEAN NUMBER CORRECT ANTICIPATIONS

Stage 1 criterion	First postcriterion trial: Forward interrupted	First postcriterion trial: Backward interrupted	First postcriterion trial: p	Criterion trial *and* first postcriterion trial: Forward interrupted	Criterion trial *and* first postcriterion trial: Backward interrupted	Criterion trial *and* first postcriterion trial: p
2	2.7	1.9	<.05	1.6	.9	<.01

6	5.6[a]	4.1	<.05	4.4[a]	3.4	<.05
8	6.4[a]	4.9	<.01	6.4[a]	4.9	<.01

[a] The $n = 10$; otherwise, $n = 20$.

of the strength of the originally learned materials, independent of the level of A–B learning.

Obviously, some pairs were either learned bidirectionally or at least had achieved sufficient bidirectional associative strength to permit successful elicitation at the time of testing. These particular pairs were, in general, idiosyncratically determined. There was a tendency for the letter–numeral combinations to produce superior performance than the numeral–letter pairs, particularly during the initial trials of Stage 2, suggesting that (*a*) despite the high association value of the materials, the equivalence of availability of the letters and numerals was not achieved at a functional level, and/or (*b*) the expected chance value of correct responses due to guessing depended upon the class of responses required.

Given the utility of the concept of backward associations as a mechanism for understanding many phenomenon in verbal learning (see Ekstrand, 1966), and the similarities between the growth of forward and backward associations in the present experiments, future research should be directed toward investigations of the susceptibility of backward learning to the major variables in forward-learning situations.

OPERANT CONDITIONING OF VASOCONSTRICTION: A VERIFICATION[1]

ROBERT M. STERN[2] AND RAYMOND P. PAVLOSKI

Pennsylvania State University

A verification of operant conditioning of unelicited vasoconstrictions was obtained for 2 separate sets of data. Significant differences were found between 30 experimental *S*s and 60 yoked control *S*s, half of whom received reinforcement identical in time and number to a given experimental *S* and half of whom received the same number of reinforcements per minute but who were never reinforced when they were vasoconstricting. Postsession questionnaire data revealed significant group differences in explanations of the response reinforcement contingencies.

Several studies have reported success in operant conditioning of vasomotor responses in animals, but only 2 published papers (Kimmel & Kimmel, 1967; Snyder & Noble, 1968) have presented evidence for operant conditioning of vasoconstriction in human *S*s; and in the Kimmel and Kimmel study, relevant statistical tests are not provided. Because of the important theoretical and methodological issues involved and the possible application of these techniques to psychosomatic disorders, it was deemed desirable to repeat the Snyder and Noble study. In the 2 experiments to follow, attention was given to possible cognitive mediators and to the role of reinforcement for the so-called noncontingent control groups (Stern, 1967).

EXPERIMENT I

Method. The *S*s were 27 female and 18 male students from introductory psychology classes at Pennsylvania State University. Right index-finger blood volume was recorded using a Beckman photoplethysmograph transducer, and respiration was recorded by means of a Parks Electronics silastic mercury strain gauge transducer. The reinforcing stimulus was a 28 v. pilot light, which was presented for 3 sec.

The *S*s were divided into 3 groups of 15 each; all were read the instructions used by Snyder and Noble (1968) except for the absence of arm electrodes and for the shortening of session length from 40 to 30 min. (no extinction period). Basically, the instructions told *S*s to relax and not try to make any voluntary responses. After the instructions were read, a 5-min. baseline period was followed by a 25-min. acquisition period, after which a questionnaire was administered. The criterion for a vasoconstriction was set independently for each *S* during the baseline period according to the procedure utilized by Snyder and Noble (1968). During this period, responses were recorded and reinforcement was omitted; the minimum amplitude response reinforced during the acquisition period was the largest baseline period vasoconstriction free from respiratory and muscular artifacts. This means that during the baseline period each *S* made 1 criterion response except for the unusual case where *S* made 2 or more "largest" responses of equal size.

Only experimental (Group 1) *S*s were reinforced for vasoconstricting during the conditioning period. Any vasoconstriction recorded within 15 sec. following a reinforcement was not reinforced. The 30 control *S*s were divided into 2 groups: each *S* in Group 2 (truly yoked) received reinforcement at the same relative time as his experimental counterpart, while each *S* in Group 3 (partially yoked) received the same number of reinforcements per minute, but never when *S* was vasoconstricting. At the end of each session, *S* was given a questionnaire to complete that contained the following queries: (*a*) What do you think made the light come on? and (*b*) If I told you that it was a response that you made that determined *when* the light came on, what do you think it was? An extinction period was not included in the sessions because of the interest in *S*s' ability to state the response reinforcement contigency. If *S*s had in fact successfully tested hypotheses about what provoked the reinforcement, an extinction period would have thoroughly confused them and invalidated the questionnaire data.

Results and discussion. Figure 1 shows the mean number of artifact-free vasoconstrictions that met the amplitude criteria for successive 5-min. periods.

The mean levels of responding for the 3 groups during the acquisition phase were 3.9, 1.8, and 0.9. Analysis of variance of the acquisition period data revealed significant group differences, $F\ (2, 42) = 12.05$, $p < .001$. Individual comparisons indicated that the level of responding of the experimental group was significantly greater than both control groups at each of the 5 time periods. The truly yoked group responded at a significantly higher level than the partially yoked group during Periods 4 and 5. Although no significant overall time effect was found, there was a significant Group $\times$ Time interaction, $F\ (7, 144) = 2.89$, $p < .01$. The latter is given with adjusted degrees of freedom (Huynh & Feldt, 1970).

Results from the postsession questionnaire data were analyzed to see whether or not the different reinforcement contingencies created group differences in regard to expectancy of reinforcement. The

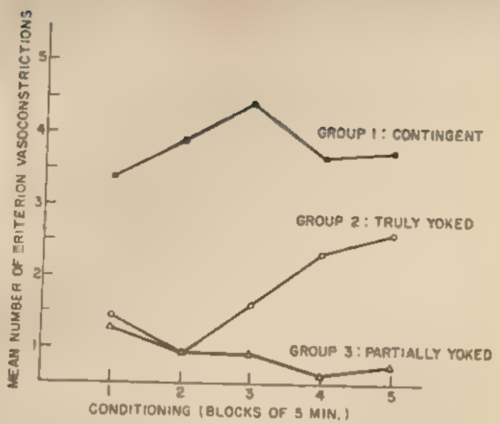

FIGURE 1. Mean number of criterion vasoconstrictions of contingent and control groups, Experiment I.

majority of *Ss* in the contingent group thought that their stimulating thoughts or bodily activity made the reinforcement light come on. Most *Ss* in both of the control groups, on the other hand, reported that the reinforcement was random or the contingency was unknown to them. The results of the questionnaire data, while not significant, were in the predicted direction. The truly yoked control group gave the expected high percentage of responses of contingency unknown. It is interesting to note that despite this reply their level of vasoconstriction increased considerably from Trial Block 2 to Trial Block 5 of the acquisition period, as shown in Figure 1. Conceivably, this increase in sympathetic responding may have been due to *Ss* persistently testing various hypotheses concerning the response reinforcement contingency.

Experiment II

The vasomotor and subjective report data of Experiment I were thought to be sufficiently interesting to repeat the experiment. More specifically, the experimental group did make significantly more vasoconstrictions than the control groups, as Snyder and Noble (1968) reported, and the questionnaire data, as mentioned above, were in the predicted direction but insignificant.

Method. The design as described above was repeated using 45 new *Ss*.

Results and discussion. Figure 2 shows the mean number of artifact-free vasoconstrictions that met the amplitude criteria for successive 5-min. periods.

The mean levels of responding for the 3 groups during the acquisition phase were 4.0, .9, and .1. Analysis of variance of the acquisition period data revealed significant group differences, F (2, 4) = 71.60, $p < .001$. Individual comparisons indicated once again that the level of responding of the experimental group was significantly greater than both control groups at each of the 5 time periods. There were no significant differences between the control groups except at Time Interval 4, where truly yoked *Ss* made more vasoconstrictions than partially yoked *Ss*. Neither the overall time effect nor the Group × Time interaction were significant.

The results of the postsession questionnaire data indicated that *Ss* in the contingent group tended to report that their stimulating thoughts or bodily activity made the light come on, whereas *Ss* in the 2 control groups reported either that they did not know what the contingency was or that reinforcement was dependent on their relaxing. These group differences were found to be highly significant, χ^2 (2) = 17.00, $p < .001$.

Conclusions

The 2 sets of data from the present experiments, collected under identical conditions, show successful modification of the rate of vasoconstrictions. This is in support of the earlier findings of Kimmel and Kimmel (1967) and Snyder and Noble (1968). Postsession questionnaire data revealed that most experimental *Ss* hypothesized correctly that the reinforcing light was contingent upon their stimulating thoughts or bodily activity, whereas most control *Ss* either thought that it was contingent on their relaxing or they did not know.

A rather curious finding which can be seen in both Figures 1 and 2 was that the performance of experimental groups reached almost the highest level during the very first 5-min. conditioning period. No ready explanation is available for this finding, even though it was observed in some of the earliest studies of operant conditioning of autonomic responses (Fowler & Kimmel, 1962).

Snyder and Noble (1968) reported a much higher level of responding than do the present authors; this may be attributed to a methodological difference. In the former study "any definite vasoconstriction not preceded by bodily movement . . . [p. 264]" was reinforced; only in the results were respiratory components and amplitude criteria taken into account. Of interest is the fact that in the present study, in which considerably fewer reinforcements were presented (since amplitude and respiratory criteria were considered during each session), results again point to successful modification of the rate of vasoconstriction. The mecha-

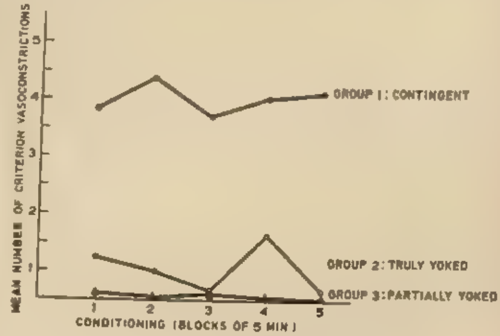

FIGURE 2. Mean number of criterion vasoconstrictions of contingent and control groups, Experiment II.

nisms by which this change comes about are not known at this time; however, an important aspect of these findings is that vasoconstriction, an autonomic response of great relevance to hypertension and other psychosomatic diseases, can be relative easily controlled and/or conditioned.

WHOLE-LIST RETENTION FOLLOWING WHOLE-PART LEARNING [1]

RONALD OKADA[2]
Atkinson College, York University, Downsview, Ontario, Canada

STEPHEN T. CAREY[3]
University of Toronto, Toronto, Ontario, Canada

After 6 trials of whole-list learning and 5 trials of part-list learning, *S*s were asked to reproduce (Experiment I) or relearn (Experiment II) the items from the whole list. Experimental *S*s, whose part list was taken from the whole list reproduced (Experiment I) and relearned (Experiment II) more whole-list items than control *S*s, whose part list did not contain any items from the whole list. These results are incompatible with Tulving and Osler's 1967 theory of the reorganization of whole-list subjective units during part-list acquisition.

Tulving and Osler (1967) have argued that the whole-part paradigm provides data that strongly support the organizational or interdependence hypothesis of free-recall learning. In this paradigm, *S*s initially learn a list of words (whole list) under conditions of free recall. Then, experimental *S*s receive further trials on a part list that is composed of a subset of the whole-list items, while control *S*s learn a part list that does not contain items from the whole list. The critical finding is that experimental *S*s exhibit less efficient learning of the part list than do control *S*s. This counterintuitive finding, Tulving and Osler maintain, results from the fact that the formation of new subjective (S) units in the part list is hindered by the prior organization of the words in different S units in the whole list. Thus, during part-list learning, experimental *S*s "must modify the units formed during whole list learning or else form completely new units [Tulving & Osler, p. 255]." Ehrlich (1970) also favors the view that the organization of the whole list is destructured during part-list learning in order that new units can be formed; however, he maintains that the whole-list organizational structure is not permanently disrupted but only temporarily inhibited. Ehrlich reached this conclusion following the demonstration that whole-list retention was not affected by several intervening trials of second-list learning in which the second list was comprised of alternate subsets of whole-list items.

If the organization established during whole-list learning is not permanently disrupted during part-list learning, one would expect that experimental *S*s should prove as able as control *S*s in their capacity to recall the whole list following part-list learning. However, if experimental *S*s must reorganize the words in the part list, and if recall is dependent upon the retrieval of S units (Tulving & Osler, 1967), then experimental *S*s must prove inferior to control *S*s at subsequent whole-list recall. The present studies were designed to compare whole-list reproduction (Experiment I) and whole-list relearning (Experiment II) for experimental and control *S*s after each group had learned its respective part list. Since there is no apparent reason to postulate that control *S*s must reorganize their whole list during part-list learning, this condition is an appropriate control for assessing whole-list retention following part-list learning.

Method. Fifty students of both sexes at the Brant Senior Public School in Toronto served as *S*s in Experiment I. They were randomly assigned to 2

[1] This research was supported by Grant A8266 from the National Research Council of Canada to the first author and a National Research Council fellowship to the second author. The authors wish to thank Doug Smith and Bill Kirkwood for arranging for the testing of *S*s.

groups of 25 each with the restriction that each of the groups have an equal number of males and females. All *S*s were seventh-grade students ranging in age 12–14 yr.

Forty-eight students of both sexes at the Bramalea Secondary School in Brampton served as *S*s in Experiment II. They were randomly assigned to 2 groups of 24 with the restriction that each of the groups have an equal number of males and females.

In Experiment I, all *S*s learned a common whole list prior to the part list. Experimental *S*s learned a part list that consisted of items randomly selected from the previously learned whole list. Control *S*s learned a part list that had no words in common with the whole list. All lists consisted of 2-syllable nouns from the 1,000 most common words in the Thorndike–Lorge (1944) word count. The whole list contained 24 words; the part list contained 12 words. In Experiment II all details were the same as in Experiment I except that experimental and control *S*s learned a different whole list and a common part list, as in the Tulving and Osler (1967) study.

The experimental and control groups were treated identically during the learning of the whole and part lists in both experiments. After standard free recall instructions were read, the first whole list was presented via tape recorder at a 1-sec. rate. Ninety seconds were allowed for written recall. There were 6 alternating training and test trials with the items computer randomized on each trial. Before the first presentation of the part list, both groups were told that "we will now go on to a shorter list. Listen carefully to each word and write down the words in any order after the list has been read." As in the Tulving and Osler (1967) study, experimental *S*s were not informed about the relationship of the second list to the first list. The part list was presented via tape recorder at a 1-sec. rate. Forty-five seconds were allowed for written recall There were 5 alternating training and test trials with items computer randomized on each trial.

In Experiment I, after the test phase following the fifth presentation of the part list was completed, *S*s in both groups were given the following instructions: "You are now to write down the words from the first or longer list that you studied in this experiment. Do not write any of the words from the second or shorter list you heard. You may write these longer list words in any order, but remember, do not write the words from the second or shorter list you studied." After 2 min. of free recall of the whole list, *S*s turned to a new sheet of paper. They were then again given the instructions to recall the whole list in an attempt to determine if there was an interaction between final whole-list recall trials and conditions. The *S*s were given 2 min. for their second recall phase

In Experiment II, after the test phase following the fifth presentation of the part list was completed, *S*s in both groups were given the following instructions: "You are now going to hear the words from the first or longer list that you studied in this experiment. Listen carefully to each word and write down the words in any order after the list has been read." Ninety seconds were allowed for written recall.

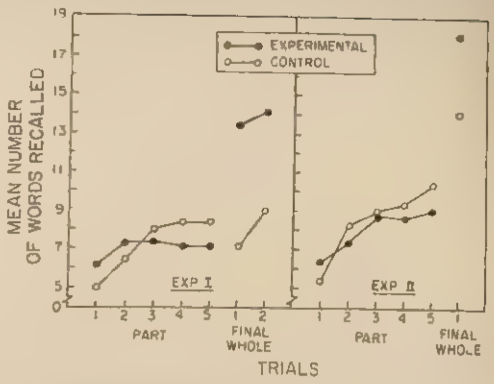

FIGURE 1. Mean number of words recalled during part-list acquisition and final whole-list reproduction (Experiment I) and relearning (Experiment II).

Results and discussion. The whole-list learning data were virtually identical for both conditions in Experiment I. An analysis of variance revealed that only trials was significant, F (5, 240) = 115.17, $p < .01$. On the sixth trial of the whole list, experimental *S*s recalled 12.7 items, while control *S*s recalled 12.4 items, F (1, 48) < 1, *ns*.

The part list data are presented in the left panel of Figure 1. Both the trials effect, F (4, 192) = 32.41, $p < .01$, and the Condition × Trials interaction, F (4, 192) = 9.86, $p < .01$, were significant.

An analysis of the final whole-list reproduction data (see left panel of Figure 1) revealed that conditions and trials were significant, F (1, 48) = 37.70, $p < .01$, and F (1, 48) = 6.11, $p < .05$, respectively. However, the Condition × Trial interaction was not significant, F (1, 48) = 3.44, *ns*.

The performance of experimental and control *S*s did not differ during whole-list learning; however, during part-list learning, experimental *S*s exhibited less efficient learning than control *S*s. These results are consistent with previous studies (Tulving & Osler, 1967). With regard to final whole-list recall, Figure 1 shows that the ability of experimental *S*s to ultimately reproduce whole-list items was not impaired by several trials of part-list learning and was greater than that of the control group. These findings are inconsistent with the hypothesis that experimental *S*s must reorganize existing S units acquired during whole-list learning and form new S units in order to learn the part list. However, it might be argued that the inferiority of control *S*s in reproducing the whole list was due to the inaccessibility of the whole-list structure as a result of *S*s' recent preoccupation with an unrelated part and consequent response set suppression of the whole list.

The results of Experiment II are relevant to this point. In this study, a relearning trial on the whole list followed whole–part learning to determine whether a single reinstatement of the whole-list context would benefit control *S*s in retrieving items

from the whole list. The whole-list learning data were virtually identical for both groups in Experiment II. An analysis of variance revealed the only significant effect to be that of trials, F (5, 230) = 137.75, $p < .01$. On the sixth trial of the whole list, experimental *S*s recalled 16.5 items, while control *S*s recalled 16.9 items, F (1, 46) < 1, *ns*.

The part-list data are presented in the right panel of Figure 1. Both the trials effect, F (4, 184) = 80.32, $p < .01$, and the Condition × Trials interaction, F (4, 184) = 7.29, $p < .01$, were significant.

On the relearning trial of the whole list (see the right panel of Figure 1), experimental *S*s recalled 18.4 items, while control *S*s recalled 14.3 items, F (1, 46) = 13.93, $p < .01$.

Again as in Experiment I, the typical negative transfer effects were found during second-list learning. Nevertheless, on the subsequent relearning trial of the whole list, experimental *S*s recalled more whole-list items than control *S*s. Thus, the additional presentation of the whole list does not alter the fact that experimental *S*s recall more whole-list items than do control *S*s. For the reasons stated earlier, this finding is contrary to the predictions from Tulving and Osler's (1967) interdependence hypothesis, which states that whole-list S units which mediate recall are modified or completely new S units are formed during part-list learning. If new S units are organized during part-list acquisition, why then do experimental *S*s show no loss of whole-list items in subsequent whole-list recall and achieve higher recall performance than control *S*s, who had no reason to modify their S units during part-list learning?

Slamecka, Moore, and Carey (1972) offered an alternative account of negative transfer in the whole–part paradigm. This account proposes that the greater discrimination that experimental *S*s are required to perform between first and second lists during part-list learning is primarily responsible for the negative transfer. Inability to discriminate among part-list items and whole-list items would depress part-list performance, producing negative transfer during part-list learning.

A list-discrimination hypothesis could also accommodate the reproduction and relearning data following whole–part learning. Since ex *S*s have an opportunity to retrieve whole-l… items during part-list learning, discriminati… them for part-list items on the basis of … of occurrence, these *S*s should be adep… ducing or relearning the whole list followi… part learning. Control *S*s, in learning a n… items during part-list learning, have no r… retrieve whole-list items and are not hind… the list-discrimination task (and thus acqui… part list more readily). However, when recall of th… whole list is required following whole–part learning, the frequency information that was established and utilized during whole-list learning (situational frequency) has begun to assimilate to its preexperimental level (background frequency) during the interpolated part-list learning (see Underwood & Freund, 1970). Thus, control *S*s exhibit forgetting of whole-list members following part-list learning.

In summary, the superiority of experimental *S*s at reproducing (Experiment I) and … (Experiment II) the items from the w… following whole–part learning may derive from … more frequent retrieval of whole-list items for experimental *S*s. In any event, since expe… *S*s retain more of the whole list following part-li… learning than do control *S*s, it cannot be the case that the organizational structure that mediates retrieval is permanently disrupted. Similar conclusions were reached in the part–whole paradigm by Carey and Okada (1973).

COMMON VERBAL QUANTIFIERS: USAGE AND INTERPRETATION[1]

MARILYN A. BORGES
San Diego State University

BARBARA K. SAWYERS[2]
University of California, San Diego

The *S*s made judgments about the meanings of 6 common quantifiers combined with different set sizes. Experiment I involved nonverbal quantity judgments; Experiment II, verbal numerosity judgments. An information integration analysis showed that *S*s' judgments followed a simple multiplying rule: the meanings of the quantifiers increased linearly with respect to the set size of the population considered. The *S*s used the quantifiers in a highly consistent manner, the only exception being the quantifier *several*, which was found to have 2 distinct usages.

The present experiments studied the usage of 6 quantifiers: *few*, *several*, *some*, *lots*, *many*, and *most*. These quantifiers are all words occurring with high frequency in the English language (AA count, Thorndike & Lorge, 1944). They are independent from one another in etymological origins (there are no common cognates or roots), and their meanings are not precisely defined in a numerical sense, e.g., *few* is more than 2, but not *many* (Onions, 1955). In addition, the use of these quantifiers is, in most cases, learned pragmatically rather than pedagogically.

Because these quantifiers are frequently used, a high degree of agreement about their meanings should exist. The main experimental questions to be answered were as follows. (*a*) Does an individual use these quantifiers in a consistent manner? (*b*) What is the extent of agreement among adults on the uses of these general quantifiers? (*c*) How do *S*s modify their interpretations of each quantifier depending upon the size of the set on which they operate?

The *S*s' tasks were to make judgments about the use of each quantifier. Judgments were based on 2 sources of information: (*a*) *S*'s conception or understanding of the meanings of the quantifiers and (*b*) *S*'s perception of the size or numerosity of the sets from which he chose. In Experiment I, values for each quantifier were determined on the basis of quantity, i.e., *S* formed subsets from various set sizes of marbles to represent each quantifier. In Experiment II, each judgment was a cognitive rating of "count" or numerosity, with the set information supplied to *S* and the quantifier response given by *S* in the form of specific integers.

Previous investigators have used statistical multiplying models for evaluating word combinations. Cliff (1959), extended by Howe (1962), studied combinations of adverbs and adjectives. However, this previous work has a serious shortcoming (Anderson, 1973) because it depends on Thurstonian scaling methods. For verbal stimuli, this method relies completely on pooled *S* data, making no allowance for individual differences. Integration theory, which takes individual differences into account, has been used in a variety of judgmental tasks (Anderson, in press; Sawyers & Anderson, 1971). The present study applied this general analytic approach to determine how *S*s integrate 2 diverse sources of information, quantifier meaning and set size, in making their judgments.

METHOD

The *S*'s task was to make a series of judgments about the quantitative meanings of 6 different quantifiers combined with 4 (Experiment I) or 5 (Experiment II) different set sizes. In Experiment I, judgments were made by taking marbles from one box and placing them in another box. In Experiment II, *S*s made judgments by specifying a particular integer for each combination of quantifier name and numerical set size.

Subjects. The *S*s were 56 students (26 in Experiment I and 30 in Experiment II) from San Diego State University.

Design and Procedure

Experiment I. There were 72 judgments for each *S*, with 6 quantifiers and 4 set sizes. The quantifiers were *few*, *several*, *some*, *many*, *lots*, and *most*. Sets of Size 12, 24, 36, and 48 were used. Each *S* served in 3 replications of this design. For each replication, *S* judged all the quantifiers in random order in 1 set size for each of the 4 set sizes. Within each replication, set size was presented in a different random order for each *S*.

The *S*s were run individually and instructed to make judgments by taking marbles from one box and putting them into another box, without actually counting the marbles. The *S*s were allowed to take as many handfuls of marbles as necessary and could rearrange the marbles between the 2 boxes until they were satisfied that their judgments were accurately reflected. Although no time limit

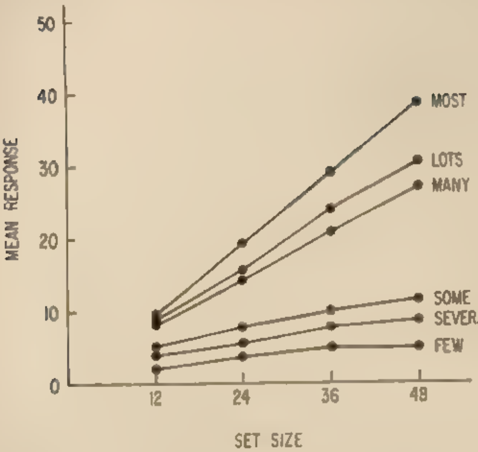

FIGURE 1. Mean numerical judgment of the 6 quantifiers for Experiment I.

was imposed, it was suggested that *S* work at a fairly rapid pace. Before the experiment began, *S*s were shown a list of the 6 quantifiers. However, *S*s were not informed of the set sizes to be used in the experiment. Two 9 × 16 × 7.5 mm. wooden boxes were placed in front of *S*. One of the boxes contained 1.5-mm. marbles, of the first set size to be judged. For each trial, a statement of the following type was read to *S* by *E*: "Take *some* of the marbles from this box [*E* pointed to first box] and put them into this box [*E* pointed to second box]." After each judgment, *E* recorded the number of marbles transferred by *S* to the second box, then returned the marbles to the first box for the next judgment. After each series of 6 judgments on one set size, *E* changed the number of marbles in the first box, and the next series of judgments was made.

Experiment II. Each *S* made a total of 90 judgments. The quantifiers used were those of Experiment I. Sets of Size 12, 36, 60, 84, and 108 were used. Each *S* judged the 30 quantifier-set-size combinations over 3 replications. As in Experiment I, for each replication, all the quantifiers were presented together in random order, for 1 set size at a time. Set size was presented in a different random order within each replication for each *S*.

The *S*s were run in a group and were instructed to specify a numerical value for each quantifier-set-size combination. The quantifiers to be used in this experiment were shown to *S*s before the experiment began; however, set sizes were not disclosed. Each *S* was given 4 packets, with 5 booklets in each packet. Each booklet contained 6 pages, with a statement of the following type on each page: "If you were to take *some* of the marbles from 84 marbles, you would take ——— marbles." The *S* filled in the blank with his numerical judgment. Only specific integers were allowed as responses. The first packet was given as practice to familiarize *S*s with the task. The *S*s were cautioned not to refer back to past judgments or change a judgment on a page that they had already turned.

RESULTS

Pilot work suggested that *S*s were relatively consistent in their usage of 5 of the quantifiers. For *several*, however, there were large individual differences, and *S*s could clearly be partitioned into a "low" group and a "high" group. Based on these preliminary results, *several* was assumed to have 2 distinct meanings, and *S*s were subdivided into a high-*several* or low-*several* category. In Experiment I, only 2 of 26 *S*s were in the high-*several* category; for simplicity, their data are not included. In Experiment II, *S*s were equally divided between the 2 groups.

Main Empirical Results

Experiment I. Figure 1 shows the mean judgments of the 6 quantifiers for the 4 different set sizes for 24 *S*s. The relative ordering of the judgments for the 6 quantifiers from low to high was *few*, *several*, *some*, *many*, *lots*, and *most*. As can be seen in Figure 1, the judgments of the quantifiers increase as near linear functions of the objective set size. A Newman-Keuls test on all ordered pairs of means for each of the quantifiers showed each quantifier to have a unique semantic meaning ($p < .01$).

Experiment II. Figure 2 shows the mean judgments of the 6 quantifiers for the 5 different set sizes. Two curves are shown for *several*: low *several*, the mean of 15 *S*s who consistently gave low estimates of this quantifier (9%–25% of the

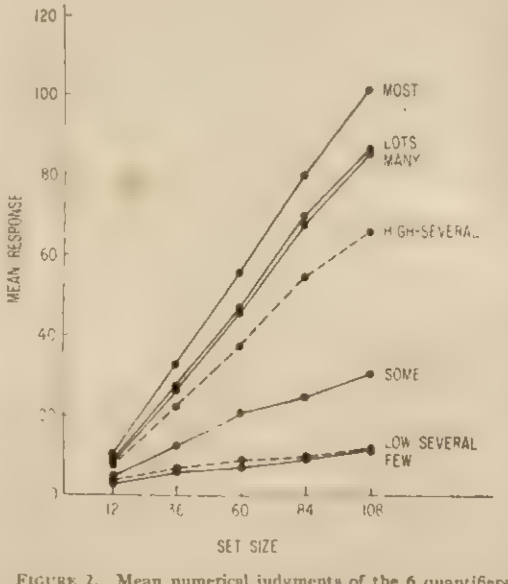

FIGURE 2. Mean numerical judgments of the 6 quantifiers for Experiment II. (For *few*, *some*, *many*, *lots*, and *most*, $n = 30$; for low *several* and high *several*, $n = 15$.)

set size), and high *several*, the mean of 15 *S*s who consistently gave high estimates (49%–77%). Newman–Keuls tests showed both high- and low-*several* *S*s to judge *lots* and *many* as having similar semantic meanings; also, low-*several* *S*s did not differentiate between *few* and *several*. However, all other quantifiers were judged as semantically unique in meaning. The ordering of the 6 quantifiers for low-*several* *S*s was *few/several*, *some*, *many/lots*, and *most*. For high-*several* *S*s, the ordering was *few*, *some*, *several*, *many/lots*, and *most*.

Model Analysis

Goodness of fit. The multiplying model from integration theory makes a simple graphical prediction: the curves of Figures 1 and 2 should form fans of straight lines, diverging as a function of increasing set size. Inspection of the curves indicates that this prediction is approximately correct.

An exact statistical test of the model is also available. Theoretically, 2 or more variables that combine in a multiplicative manner will show an interaction concentrated in the bilinear (Linear × Linear) component, but the residual should be nonsignificant. A test on the interaction residual is primary, therefore, in that a significant residual is direct evidence against the model. In Experiment I, the overall interaction (Set Size × Quantifier) was found to be very large, F (15, 345) = 101.36, $p < .01$. The residual interaction was found to be nonsignificant, F (14, 345) = 1.08. The overall Set Size × Quantifier interactions of Experiment II for both the low-*several* and high-*several* groups were also large, F (20, 280) = 203.52, and F (20, 280) = 75.19, respectively, both ps $< .01$. The residual interaction of the low-*several* group was only marginally significant, F (19, 280) = 1.70, $p = .05$. The residual interaction of the high-*several* group was nonsignificant, F (19, 280) = .47. Thus, the data give considerable support to the multiplying model: each quantifier is integrated with set size by a simple multiplying rule.

Functional scale values. Since the marbles were given as a heap in the box, it was not possible to assume without evidence that the actual objective number of marbles in the box was equal to the effective subjective number of marbles that *S* used in making his response. Thus, factors of visibility or manual accessibility might produce differences between the subjective and objective values. The functional measurement analysis from integration theory provides subjective values for both stimulus variables. This analysis showed that, for set size, subjective number was nearly a perfectly linear function of actual number. The functional scale values of the quantifiers *few*, *several*, *some*, *many*, *lots*, and *most*, respectively, were, for Experiment I, .16, .26, .33, .60, .68, and .81; and for Experiment II, .15, .17 (low *several*) and .63 (high *several*), .34, .77, .79, and .92.

Discussion

In both Experiments I and II, the multiplicative model of integration theory was found to be highly descriptive of the way in which *S*s integrate the meanings of each quantifier with set-size information. A high level of consistency was found in the use of verbal quantifiers for each individual *S* and, with the exception of *several*, across *S*s as well. There were also strong indications that *S*s judged each of the quantifiers to represent a consistent proportion of the total set size. This proportional relationship existed regardless of whether the task was a quantity judgment task (Experiment I), or a verbal numerosity judgment (Experiment II).

That *several* was found to have 2 distinct meanings was quite unexpected. A number of *S*s were interviewed, and each stated his strong belief that his particular use of *several* was the only "correct" usage, but no clues were obtained to explain this difference. However, the data show that both low-*several* and high-*several* *S*s use the word consistently in a variety of contexts. Specifically, high-*several* *S*s always judged *several* to mean more than low-*several* *S*s, regardless of context.

In Experiment I, all 6 quantifiers were judged to have distinctly different meanings. However, in Experiment II, the meanings of low *several* and *few* did not significantly differ, nor did the judgments of *lots* and *many*. The most likely explanation for this difference lies in the nature of the tasks. In Experiment I, *S*s made an intuitive judgment of relative quantity for each quantifier based on the perceptual mass of the total set of marbles. In Experiment II, *S*s had to give an exact number for each quantifier based on only verbal information about the total set size. Presumably, this was more difficult in that (*a*) usually, no specific number or percentage is associated with quantifiers, and (*b*) such precise numerosity judgments fall outside *S*s' normal range of experience with the quantifiers. It is possible that the necessity of making numerosity responses to the quantifiers rather than quantity judgments produced the less specific distinctions among the quantifiers.

In summary, adult *S*s were found to use the quantifiers in a highly consistent manner, with the exception of the quantifier *several*, which had 2 distinct interpretations. Information relating quantifier and set size was seen to follow a simple multiplying rule, i.e., usage of these quantifiers seems to be determined by each quantifier's proportional relationship to the total set size. While small variations in the meanings of words across people is to be expected, the surprising bimodal distribution of the meaning of *several* raises an important question about the objectivity of word meanings.

SHORT-TERM MOTOR MEMORY AS A FUNCTION OF FEEDBACK AND INTERPOLATED ACTIVITY [1]

L. BURWITZ [2]
University of Illinois

A test was made of the hypothesis that short-term motor forgetting could be found on 1 trial, in the absence of interference, if covert rehearsal were sufficiently restricted. The covert-rehearsal process was impaired by either reducing response-produced feedback and/or requiring attention toward a rehearsal-preventing activity during the retention interval. The task used was linear lever positioning. Two conditions of feedback and 3 levels of interpolated activity gave 6 independent treatments, with 19 *S*s each. Feedback involved the presence of audition, proprioception, and vision (APV) or their absence (−APV). Interpolated activity was a 5-sec. rest or immediate recall, a 90-sec. rest, and a 90-sec. digit classification. Under −APV, there was forgetting over the unfilled retention interval and no increased forgetting with interpolated activity. Under APV, there was no forgetting at rest, but recall decrements occurred following interpolated activity. The results were interpreted in terms of trace decay theory, and the importance of covert rehearsal for motor retention was discussed.

The trace decay theory of forgetting has received little experimental attention in short-term motor memory research. Only 2 studies have used a single-trial learn–recall design, which eliminates the possibility of interference. In these studies, Williams (1971) reported no forgetting in the absence of prior learning, while Adams, Marshall, and Goetz (1972) found evidence of trace decay under minimal feedback conditions. Adams et al. suggested that impoverished feedback produced a weak image or perceptual trace and, although they made no attempt to measure the strength of the trace, they concluded that the weak trace decayed over time. According to Brown (1958), decay is not a function of time per se, but it is rather a consequence of covert rehearsal restrictions. Thus, impoverished feedback appears to impair covert rehearsal.

If one assumes that *S* is unable to rehearse a weak perceptual trace, but that he is able to rehearse a stronger image, one would expect on the basis of the trace theory that interpolated rehearsal-preventing activity would differentially effect recall under impoverished and augmented feedback conditions. In support of this contention, Posner and Konick (1966) and Posner (1967) found that blind movements (minimal feedback) were forgotten over an unfilled retention interval and unaffected by interpolated activity, while visually guided movements showed forgetting only after rehearsal-preventing activity. Posner and Konick and Posner used a repeated measures design (48 trials in 50 min.); consequently, their results do not provide conclusive evidence of trace decay, since such designs contain a built-in potential for proactive interference (cf. Adams et al., 1972). In the present study, a single-trial learn–recall design was employed to eliminate the possibility of interference and to provide a clean test of the trace decay theory, which predicts forgetting under impoverished feedback and interpolated noninterfering activity because of covert-rehearsal restrictions. In addition, the strength of the perceptual trace was assessed under impoverished and augmented feedback conditions.

Method. One hundred and fourteen right-handed male undergraduate students were randomly assigned to 1 of the 6 independent conditions of the 2×3 factorial design, with 19 *S*s per cell. The 2 levels of the first factor involved the presence of audition, proprioception, and vision (APV) or their absence (−APV), and the second factor was

a 5-sec. rest or immediate recall, a 90-sec. rest, and a 90-sec. digit classification.

Linear lever positioning was used as the memory task, and the apparatus was essentially the same as that described by Adams et al. (1972). On top of the lever, which ran along a 15-in. trackway, was a button that *S* depressed to move the carriage and released to lock it in place for the purpose of measurement. The apparatus was located behind a 1-way mirror and *E* was able to manipulate visual feedback by altering the lighting conditions on either side of the mirror. All lever movements were from right to left and were essentially frictionless (−APV) or were resisted by a coiled clock spring with a pull of 1.75 lb. (APV). Auditory feedback was eliminated when necessary (−APV) by white noise played through earphones at 120 db.

The experiment was conducted in 2 stages, the first of which involved instructions and a 20-sec. practice trial on the digit classification task. The digits were printed on a sheet of paper located on the wall to the left of *S*'s chair at approximately eye level. On the command "digit," *S* turned his head and began reading down the first of 4 columns of 2-digit numbers, verbally indicating as fast as possible whether each was high or low (above or below 50) and odd or even.

The second phase included linear-lever-positioning instructions, a demonstration (14 in.) and 2 movements, which were separated by a retention interval of 5 or 90 sec. The first movement was to the criterion (8 in.), which was defined by a stop, and the second was to where *S* thought the stop had been. At the end of each movement, *S* released the button on top of the lever and maintained his grasp for another 2 sec. before being instructed to place his right hand on the pad located on the table in front of him. The 2 movements were made under identical feedback conditions, with vision and white noise being manipulated for a period that extended from 2 sec. prior to movement initiation through 2 sec. after button release. The retention interval was timed from button release, and during this period, digit classification *S*s performed the interpolated task, while rest *S*s were required to face the mirror. All *S*s kept their right hands on the pad throughout the retention interval, and *E* returned the lever to the start.

After the 2 movements, *S* was asked to estimate the direction and magnitude of his error from the criterion. The absolute difference between the actual and estimated algebraic error scores was taken as an indication of *S*'s ability to accurately estimate his own performance. This score was assumed to reflect the strength of the perceptual trace since *S* is unable to accurately estimate performance without a strong trace. Finally, an interview was conducted to gather information on the strategy *S* used to position the lever.

Results. Analysis of variance of the absolute error scores found the main effects of both feedback and interpolated activity to be significant: $F(1, 108) = 12.55$, $p < .001$; and $F(2, 108) = 4.27$, $p = .02$, respectively. Table 1 indicates the overall superiority of the APV condition (4.9) over the −APV treatment (9.1). Post hoc analysis, using Duncan's new multiple range test, revealed that the interpolated digit classification condition (9.1) recalled significantly ($p < .05$) less than the immediate recall group (4.9), and that there were no other significant differences between the interpolated activities.

TABLE 1

Mean Absolute Retention Test Error (⅛-in. units)

Interpolated activity	Feedback condition		Grand *M*
	APV	−APV	
None (immediate recall)	3.63	6.16	4.90
90-sec. rest	3.42	10.53	6.97
90-sec. digit classification	7.68	10.47	9.08
Grand *M*	4.91	9.05	

Note. Abbreviations: APV indicates the presence of audition, proprioception, and vision; −APV indicates their absence.

The Feedback Condition × Interpolated Activity interaction was not significant, $F(2, 108) = 1.61$, $p = .20$. Although the interaction was not significant, it was expected on the basis of the trace decay theory that recall decrements would occur over an unfilled retention interval under −APV, and that forgetting would occur only after interpolated rehearsal-preventing activity under APV. To test these theoretically based a priori assumptions, 2 orthogonal tests were made, using the t ratio with the mean square error from the analysis of variance as the error term to give 108 *df*. The first test indicated that under −APV, decrements in recall were significantly ($p < .05$) larger after the 90-sec. rest (10.5) than at immediate recall (6.2). The second test revealed that under APV, there was significantly ($p < .05$) more forgetting after the 90-sec. digit classification (7.7) than after the 90-sec. rest (3.4).

The same analysis was run on algebraic error as on absolute error, and none of the tests were significant. Averaging over all interpolated activities, the mean algebraic error was −1.0 for APV and −2.9 for −APV. Averaging over feedback conditions, the means for interpolated activities were −1.1, −2.8, and −2.1 for the 90-sec. digit classification, 90-sec. rest, and 5-sec. rest, respectively.

The analysis of variance of *S*'s ability to accurately estimate his own performance (absolute difference between actual and estimated algebraic error scores) found both main effects significant: for feedback, $F(1, 108) = 7.71$, $p = .01$; and for interpolated activity, $F(2, 108) = 4.57$, $p = .01$. Table 2 indicates that −APV produced a weak perceptual trace (7.6) compared to that developed under APV (4.7). Furthermore, post hoc analysis revealed that the perceptual trace was significantly ($p < .05$) weaker following interpolated activity

TABLE 2

Absolute Difference (⅛-in. units) between Actual and Estimated Algebraic Error Scores

Interpolated activity	Feedback condition		Grand *M*
	APV	−APV	
None (immediate recall)	2.95	6.00	4.47
90-sec. rest	4.37	6.90	5.63
90-sec. digit classification	6.68	9.84	8.26
Grand *M*	4.67	7.58	

Note. Abbreviations: APV indicates the presence of audition, proprioception, and vision; −APV indicates their absence.

(8.3) than at immediate recall (4.8). None of the other differences were significant.

Discussion. The present results lend credence to the trace decay theory of forgetting, since recall decrements occured with 1 learn–recall trial in the absence of apparent interference. In support of Adams et al. (1972), there was no forgetting over the unfilled retention interval when feedback channels were intact (APV), but significant decrements in recall were induced by attenuating feedback (—APV). The manipulation of feedback also influenced *S*s ability to accurately estimate his own performance. This ability was assumed to reflect the strength of the perceptual trace, and, as Adams et al. hypothesized, the trace under impoverished feedback was significantly weaker than under APV. Apparently, minimal feedback produced a weak perceptual trace, which decayed over the unfilled retention interval because it was not rehearsed.

If one assumes that covert rehearsal was not possible following −APV but was possible after APV, then one would predict on the basis of the trace decay theory that interpolated rehearsal-preventing activity would produce no more forgetting than would rest under −APV, but that it would cause increased forgetting under APV. The results, which provided support for the hypothesis and additional evidence of trace decay, were in accord with the findings of Posner and Konick (1966) and Posner (1967) and although these studies, because of their built-in potential for proactive interference, do not offer direct evidence of trace decay, they certainly do not contradict the theory.

Short-term motor memory is apparently influenced by covert-rehearsal opportunities. The mechanism for such rehearsal is not clear at present, although it appears plausible to suggest, on the basis of the introspective reports of *S*s, that verbal labels or imaginal mediators are necessary for motor retention. The present interview data concurred with the findings of Posner and Konick (1966) and favored the imagery position, but additional research is required to substantiate this visual encoding hypothesis.

ABSTRACTION OF UNIDIMENSIONAL CONCEPTS FROM LARGER CONCEPTUAL SYSTEMS[1]

VITO MODIGLIANI[2]

Wesleyan University

Stimuli consisting of 2 systems, a face and a pipe, were used. Each system consisted of 3 bivalued dimensions and 2 constant values. Together, the 2 systems made up a meaningful figure, a "face smoking a pipe." During an initial training phase, one of the dimensions was made relevant in a concept identification type task. In the subsequent concept conservation task, 48 *S*s were found to conserve less in response to transformations operating on the system containing the relevant attribute than to identical types of transformations operating on the other system. The findings were interpreted as indicating the importance of stimulus structure in determining the abstraction of unidimensional concepts from larger conceptual systems.

Recently, Modigliani (1971) studied how bounded- s affected the conservation of simple unidimen- nal concepts. In that study bounded stimuli nsisting of 4 bivalued dimensions were potted wers, each made up of flower pot, stem, leaves, d blossom. Unbounded stimuli were obtained rom the bounded ones by redrawing the latter a disjointed manner. Concept conservation was ower with bounded than with unbounded stimuli. he problem with this manipulation of bounded- ess is that it is not clear to what extent the effect was determined by the perceptual nature of the stimulus manipulation, rather than by conceptual boundedness per se.

In the present study, boundedness was manipu- lted both at the stimulus level, as in Modigliani 1971), and conceptually, as follows. Consider drawing depicting a "face smoking a pipe." h a stimulus is an overall bounded set of at- utes and could be perceptually unbounded ac- ding to the Modigliani procedure. On the other hand, the stimulus could also be considered as consisting of 2 separate systems, the face and the pipe, each of which constitutes a bounded set of attributes in itself. If this were so, it could be expected that a higher degree of boundedness obtained between 2 stimulus elements belonging to the same system, e.g., the pipe, than between 2 elements belonging to different systems, e.g., one to the pipe, the other to the face. Thus, the hypothesis tested in the present study was that if the concept to be conserved was a pipe element, then transformations operating on other pipe elements should be more disrupting (lead to less conservation) than similar transformations oper- ing on face elements, and vice versa. This hypothesis will be referred to as the conceptual boundedness hypothesis because it depends solely on how *S* interprets the stimulus, not on any perceptual manipulation of it.

Method. The design of the experiment was a $3 \times 2 \times 18$ factorial, the independent variables being age, perceptual boundedness, and transformations, respectively. The 3 age levels included children from the first, third, and sixth grades. The 2 perceptual boundedness levels were those used by Modigliani (1971), stimuli being either bounded or unbounded, and the transformations are described below. The first 2 factors were between-*S*s and the third within-*S*s variables.

The *S*s were 48 children, 16 from each of the 3 grades, drawn from 2 schools in Middletown, Connecticut. Within each age, *S*s were randomly assigned to the experimental conditions.

The experiment followed the same pattern as that of Modigliani (1971) and consisted of a training phase followed by a conservation test phase. In the training phase, *S*s learned to categorize stimuli according to a single relevant dimension—the shape of the eyebrows for half of them and the brightness of the pipe bowl for the other half. The training stimuli consisted of 32 outline figures drawn on 21.7×28 cm. sheets of white paper. Each drawing consisted of 10 values, of which 4 were constant, i.e., the same for all stimuli, and the remaining 6 were values from bivalued dimensions. Each of the 2 stimulus systems, the face and the pipe, consisted of 3 (varying) dimensions and 2 constant values. The 3 face dimensions were the shape of the eyebrows, the shape of the nose, and the shape of the mouth. The shape of the eyes and the face contour were constant face values. The 3 pipe dimensions were the brightness of the pipe stem, the brightness of the bowl, and the shape of the smoke the pipe emitted. The constant dimensions of this unit were the overall shape of the pipe and the shape of the bowl rim. Values were drawn at fixed positions in both conditions of perceptual boundedness. The 32 training stimuli comprised a random sample of the 64 possible stimuli, with the restriction that half contained one relevant value and the other half, the other relevant value.

The conservation phase stimuli consisted of 28 drawings, 10 of which were randomly selected from those used in the training phase, and the rest representing 1 transformation each. Trans-

[1] This research was made possible by a Wesleyan University grant in support of scholarship. The author wishes to thank Marjory S. Daltry, Clem M. Green, Harold Kaplan, and Anthony LaBella for their collaboration in providing *S*s for this research, and Robert S. Feldman for running the *S*s.

TABLE 1

Mean Percentage of Conserving Responses as a Function of *Other* versus *Same* System Transformations and Perceptual Boundedness

System operated on by transformations	Perceptual boundedness	
	Unbounded	Bounded
Other	79.2	75.0
Same	80.0	53.3

formations were obtained by adding, deleting, and substituting new values for old ones in the training stimuli. For present purposes, only the first 10 transformations will be described in detail. Five of them operated on elements belonging to the system not containing the relevant attribute, referred to as the *other* system. The 5 remaining operated on elements belonging to the system containing the relevant attribute, the *same* system. For each transformation in the *other* system group there was an exact replica in the *same* system group, with 1 exception. The 5 transformations in the *other* system group were: (*a*) deletion of 1 irrelevant value, (*b*) deletion of 2 irrelevant values, (*c*) deletion of the entire *other* system, (*d*) deletion of the system's 2 constants values, and (*e*) substitution of a new value for one of the old constant ones. The same transformations were used to operate on the *same* system, the exception being that instead of deleting the entire *same* system, the relevant value was never deleted.

A test of the conceptual boundedness hypothesis entailed a comparison between these 2 groups of transformations as a function of perceptual boundedness. When the stimuli are perceptually bounded, the distinction between *other* and *same* systems is meaningful, but is effectively lost when the stimuli are perceptually unbounded. The conceptual boundedness hypothesis, therefore, predicts an interaction between perceptual boundedness and transformations operating on the *other* vs. the *same* system: there would be a significant difference due to these 2 types of transformations for bounded but not for unbounded stimuli.

Two random sequences of the 28 conservation test cards were used with the restriction that no more than 2 training cards appear consecutively. Half of the *S*s were randomly assigned to each order. A 28 × 28 × 45 cm. box, divided into 3 compartments, the middle of which was painted gray, a lateral one blue, and the third green, was used to test *S*s.

The procedure was almost identical to that used by Modigliani (1971). The only difference was that while Modigliani presented the task as one in which *S*s had to tell whether cards were taken from boxes of different colors, the present task was one of putting cards *into* such boxes. In outline, *S* was told in the training phase that each card would go into either the green or the blue compartment of the box in front of him. He was shown an example consisting of a pair of stimuli differing only along the relevant dimension, and was told which of these 2 stimuli went into the green and which into the blue compartment. After *S* examined the stimuli for as long as he wished, he was run to a criterion of 31 out of 32 correct classifications of the training stimuli, one at a time. He was then told that more cards would be shown and that he could now put any of them into the gray compartment if he so wished.

Results and discussion. A placement of a test card into the appropriately colored (blue or green) compartment was defined as conserving and scored as 0. A placement in the gray box was a nonconserving response and was scored as 1. All *S*s but 2 classified all old cards in the conservation phase correctly. In each of the 2 exceptions, *S* made one error that consisted in each case of placing a green card (different for each *S*) in the blue compartment. These errors were considered as temporary slips of memory, and these *S*s' responses to the actual test cards were included in the analysis of the data.

An overall analysis of variance was performed on the data. Only results pertinent to the conceptual boundedness hypothesis will be reported. There were no age effects related to the hypothesis being tested. The mean percentages of conserving responses as a function of perceptual boundedness and transformations in the *other* and the *same* systems, are shown in Table 1. Planned comparisons showed that the 2 mean percentages in the top row did not differ from one another ($F < 1$) but that those in the bottom row did, $F(1, 714) = 19.86$, $p < .01$. Furthermore, the 2 means in the left column did not differ from one another ($F < 1$), while those in the right column did, $F(1, 42) = 21.33$, $p < .01$. Thus, the bottom right mean is significantly different from the other 3 means, which do not differ from each other.

The above results entirely confirmed the conceptual boundedness hypothesis. It seems that the most important aspect of this confirmation is the demonstration that the internal structure of a stimulus, considered as a conceptual system, may affect the way *S*s abstract a simple concept from the larger conceptual framework. Stimulus structure, with the exception of salience (e.g., Trabasso & Bower, 1968) has received little attention in the experimental literature on conceptual behavior. By and large, stimuli are considered as a collection of attributes, some being more salient than others, but having no structural organization of a more complex sort. One exception to this statement is provided by Sutherland (1968). His views were later summarized as follows: "a picture of a man can be decomposed into head, trunk, arms, etc.; head into cheeks, eyes, ears; and at the lowest level, objects are decomposed into segments (or edges) and textures [Sutherland & Mackintosh, 1971, p. 53]." This hierarchical description is remarkably similar to one independently favored by the author with regard to the stimuli used in this experiment. Here the perceptually bounded stimuli are thought of as con-

sisting of (at least) 3 levels. The top level represents the entire stimulus, a face smoking a pipe. The middle level represents the 2 independent systems, the face and the pipe. The bottom level represents the single attributes, the shape of the eyebrows, the brightness of the pipe, etc. Transformations in the present study operated on elements at this bottom level. However, their effect depended on the locus of the attribute(s) operated upon, with respect to the next higher level in the hierarchy, as was the case with perceptually bounded stimuli. While the present results demonstrate in only 1 instance that the abstraction process depends on a level above the one at which the element to be abstracted is located, these results *do* raise the problem of stimulus structure as a potentially important one in the experimental analysis of conceptual behavior.

SCANNING FOR SIMILAR AND DIFFERENT MATERIAL IN SHORT- AND LONG-TERM MEMORY[1]

C. JAMES SCHEIRER[2] AND MICHAEL J. HANLEY

State University of New York at Binghamton

The *S*s were required to retain a short list of items for an entire experiment while processing successive different short lists of items in the Sternberg paradigm. It was found that reaction time was linearly related to set size for both the permanent list and the immediate lists, but that the slope of the function depended on whether the type of material retained permanently was similar to or different from the successively processed lists. The results are discussed in terms of Sternberg's exhaustive-scanning hypothesis.

The scanning paradigm has been used by Sternberg (1969) and others to investigate search and retrieval processes in memory. In the scanning paradigm, *S* is presented, serially, with a short list of items. Immediately after the presentation of the list, *S* is presented with a single item (probe) and is required to state whether the probe was a member of the list just presented. In this task, performance is practically error free, and response latency is the dependent variable of major interest.

Logically, one would expect the items presented in a scanning task to reside in short-term store (cf. Atkinson & Shiffrin, 1968). Sternberg (1969, Experiment V) and Forrin and Morin (1969) have investigated retrieval of materials in short-term store (STS) and long-term store (LTS) using the scanning paradigm. Sternberg's results led him to postulate that material residing in LTS at the time of the test is transferred item by item to STS, where it is scanned exhaustively. Forrin and Morin, on the other hand, found evidence for independent access to STS and LTS. It must be noted that, although an STS–LTS distinction is discussed by many writers, there does not appear to be an empirical distinction between processing in LTS and processing in STS in the scanning paradigm. Forrin and Morin presented materials assumed to reside in LTS and STS; they found that *S*s were able to access the sets of materials independently. Kaminsky and DeRosa (1972) found that when *S*s were presented a mixed 6-item list of letters and numbers they were able to partition this list, and they appeared to operate on each sublist independently. Thus, for these studies, the utility of a distinction between STS and LTS on other than operational grounds is unclear. Glanzer (1971) has made much the same point in his distinction between LTS and STS as theoretical constructs and long- and short-term memory (LTM and STM) as operational distinctions.

The question thus arises as to the possibility of empirically separating scanning functions in LTS and STS. The present study attempted such a differentiation. It was felt that a critical factor in producing the independent processing found by other *E*s might be the discriminability of the stimulus sets used. Therefore, in this study, the discriminability of stimulus sets was varied systematically.

Method

The materials used in this study were 2-digit numbers, with each digit chosen randomly from the pool 2–9, and letter bigrams, with each letter chosen randomly from the pool P–W. In no case were both items of a pair identical. Two complete sets of materials were constructed, and half of the *S*s received each set. Items were presented on pairs of IEE display units controlled by an Iconix system controller for .8 sec., with .2 sec. between items. After all of the items on a list had been presented, there was a 2-sec. pause until the test item (probe) appeared. One second prior to the presentation of the probe the word *test*, written in red, appeared above the display units. The probe terminated after 3 sec. There followed an intertrial interval of 11 sec., at which time the word *ready* appeared above the display units. One second later the presentation of the next list of items began. One hundred and twenty such lists were presented to each *S*. The *S* responded to the test stimulus (probe) by depressing 1 of 2 buttons located on a box in front of him. The buttons were labeled *yes* and *no*, corresponding to positive and negative probes.

Experimental conditions. There were 3 experimental conditions, control (C), same (S), and different (D). Condition C was a replication of the basic Sternberg (1969) paradigm. The *S*s received lists of 1, 2, or 3 items, followed 2 sec. later by a probe. An *S* saw only a single type of material. Sixteen *S*s were run in this condition; for 8 *S*s, all lists were composed of digits, while for the other 8 *S*s, all lists were composed of letters. This condition can be conceptualized as a 0 item in the LTM set condition.

Condition S *S*s were required to memorize a list of 1, 2, or 3 items prior to the start of the experiment; this list constituted the LTM set. During the course of the experiment, Condition S *S*s received lists of 1, 2, or 3 items of the *same* type of material they had previously memorized in the LTM set; these items constituted the STM set. Half of the *S*s received lists of numbers in both the STM and LTM sets, and half of the *S*s received lists of letters in both the STM and LTM sets. In Condition *S*, a positive probe was defined by the instructions to include items in either the LTM or STM set; that is, items that had been memorized prior to the start of the experiment and items on the list most recently presented were to be responded to when they were presented as probes by pressing the *yes* button. Negative probes were defined as items not presented in either the LTM or the STM set. Negative probes were, however, always of the same material as that in the LTM and STM sets. Twenty-four *S*s were run in Condition S, 8 with each of the 3 different length LTM lists. The procedures for *S*s in Condition D were identical to those for *S*s in Condition S except that the STM set lists were composed of material of the *opposite* type from that memorized in the LTM set. That is, half of the *S*s received lists of numbers in the LTM set and lists of letters in the STM set, while the other half received lists of letters in the LTM set and lists of numbers in the STM set. Long- and short-term memory items were tested equally often.

For *S*s in Conditions S and D, the LTM set was written in block capital letters on a single 5 [illegible] index card. The *S*s were instructed to memorize the items on the card and were allowed to keep the card with them during the course of the experiment. The *S*s were instructed to respond to probes as rapidly as possible, consistent with errorless performance. There were 64 *S*s, all introductory psychology students at the State University of New York at Binghamton who participated in the experiment as part of the course requirement.

Results and Discussion

The data from the first 12 trials for each *S* were discarded. Mean and harmonic mean latencies for each condition were then computed on the remaining 108 trials for each *S*. Only data from correct responses were utilized; error rates were uniformly low, ranging from 3.6% in Condition C to 2.6% in Condition S and 2.2% in Condition D. Identical patterns of results were found for mean and harmonic mean latencies, so harmonic mean latencies were used throughout this report. These measures were preferred, since they weight short latencies disproportionately. This was felt to be desirable, as latency scores tend to be positively skewed. Harmonic means tend to reduce the size of scores relative to arithmetic means. In general, they differ [illegible] from arithmetic means as the size of the mean decreases. Thus, while differences were small, harmonic mean latencies tended to yield smaller values of reaction time (RT) and slopes steeper than arithmetic means. For example, the best fitting (least squares) straight line relating reaction time to set size (s) for Condition C was RT = 637 + 160s for harmonic mean latencies, and RT = 668 + 172s, for arithmetic mean latencies.

Condition C. The results of this condition, based on the responses of 16 *S*s, replicated the basic Sternberg (1969) results. As is usual in that paradigm, RT was a linear function of list length, with the linear component of the trend accounting for 99.[illegible]% of the variability in the case of positive probes and 99.6% of the variability in the case of negative probes. The best fitting (least squares) straight line was RT = 588 + 158s for positive probes, and RT = 686 + 161s for negative probes. It should be noted that these slopes are considerably larger than those found by Sternberg with single-digit numbers or by Swanson, Johnsen, and Briggs (1972) with pairs of digits. They are also substantially larger than those found previously by this *E* using similar procedures. No reason for the differences obtained in this study are apparent.

Condition D. An overall analysis of variance of the harmonic mean latencies in Condition D showed that positive probes were responded to faster than negative probes, 1029 msec. vs. 1148 msec., $F(1, 12) = 59.39$, $p < .01$; and that list length in the STM set was a significant source of variance, $F(2, 24)$

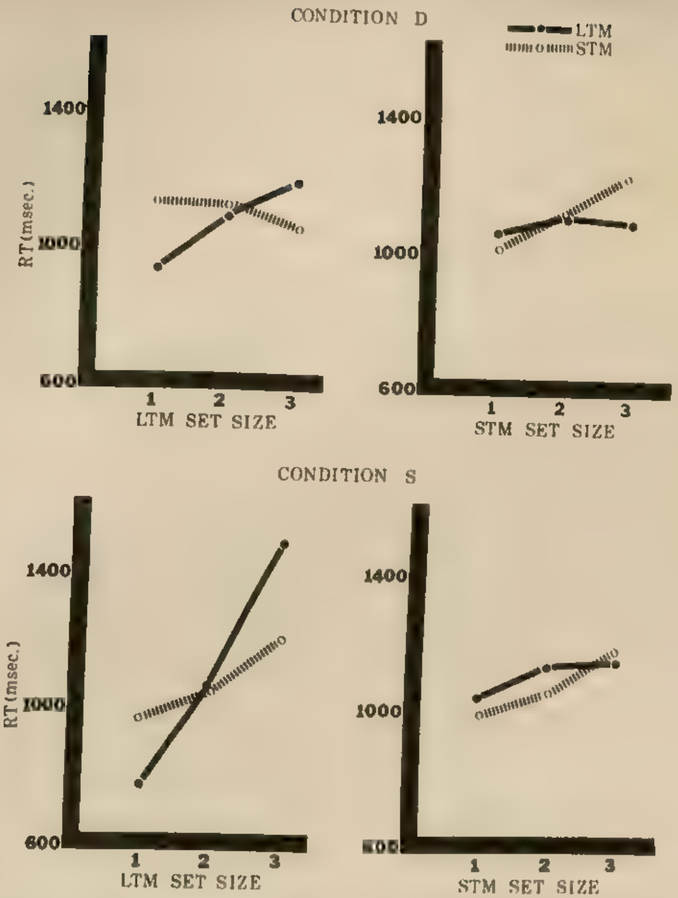

FIGURE 1. Reaction time (RT) for correct responses from the long- and short-term memory (LTM and STM) sets in Conditions different (D) and same (S) as a function of set size.

$= 68.11$, $p < .01$, with 97.2% of the variability accounted for by the linear trend. There were no significant deviations from linearity, F (1, 24) $= 3.74$, $p > .05$. It might be noted that list length in LTS was also a substantial source of variability, but since this factor was between *Ss*, the design lacked power in the test of this component, F (2, 12) < 1. The only other sources of variability to reach significance were the LTM Set List Length × Locus of Test (LTM or STM) interaction, F (2, 12) $= 16.90$, $p < .01$, and the STM Set List Length × Locus of Test interaction, F (2, 24) $= 26.90$, $p < .01$. These interactions, illustrated graphically in the top portion of Figure 1, indicate that memory scanning occurred for both the LTM and STM items, but that changing the size of the memory set in the nontested locus had no effect on speed of recall. The slope of the scanning function in the LTM set was 124 msec/item, while that in the STM set was 104 msec/item. A specific planned comparison, using a combined within-*Ss* error term, indicated that these slopes did not differ reliably, F (1, 132) $= 1.86$, $p > .05$; and that the size of the memory load in the nontested store did not affect the speed of recall, F (4, 132) < 1.

The data presented in Figure 1 suggest that *Ss* access the STM and LTM material independently when that material is highly discriminable. This conclusion follows from the fact that in Condition D there is no effect of LTM set size on scanning in the STM set, and no effect of STM set size on scanning in the LTM set. These results thus replicate the results of Forrin and Morin (1969). It should be noted, however, that although it would seem likely that STM and LTM sets would reside in different memory states (STS and LTS) because of the amount of information and operations involved in the task, this conclusion is not forced by the data. It is possible that all items are held in active memory, but that discriminable subsets of items are acted on independently (Kaminsky & DeRosa, 1972).

Condition S. An overall analysis of variance on harmonic mean latencies revealed that list length in the LTM set was a significant source of variance,

F (2, 12) = 5.53, $p < .05$, with 97.0% of the variability in the effect accounted for by the linearity of the trend. Deviations from linearity failed to reach significance, F (1, 12) < 1. Harmonic mean latencies of the 3 types of test items also differed significantly, F (2, 24) = 21.82, $p < .01$, with means of 1071 msec. for positive probes in the STM set, 1102 msec. for positive probes in the LTM set, and 1243 msec. for negative probes. Specific comparisons among these conditions revealed that negative probes were responded to reliably slower than positive probes, F (1, 24) = 42.15, $p < .01$, but RT to positive probes did not differ according to memory set, F (1, 24) = 1.24, $p > .05$. List length in the STM set was also a significant source of variability, F (2, 24) = 20.35, $p < .01$, with the linear component of trend accounting for 99.98% of the variability in the effect. The only other sources of variability to reach significance were the LTM Set List Length × Test Conditions interaction, F (4, 24) = 15.83, $p < .01$, and the STM Set List Length × Test Conditions interaction, F (4, 48) = 3.14, $p < .05$. These effects are presented graphically in the bottom portion of Figure 1.

The function relating RT to set size in the LTM set in Condition S was RT = 380 + 361s. This function was basically linear in form, accounting for 99.3% of the variability associated with difference in set size. The function obtained for this condition has a slope substantially larger and an intercept substantially smaller than that found in any other condition. Using Sternberg's (1969) interpretation of slope and intercept values, the LTM items in Condition S are accessed faster than those in any other condition (including Condition C, access to a single set of items), but are scanned more slowly. While the slow scanning rate for LTM items appears plausible, and in fact replicates Sternberg (Experiment V), the very fast access time appears difficult to handle within Sternberg's model.

One possible explanation of this data is that *Ss* might be disregarding the classification of items into LTM and STM sets. The best fitting straight line through these points is RT = 657 + 104s, which accounts for 91.2% of the variability in prediction. One interpretation of this function is that material from the LTM set is held in the same locus as items in the STM set; the total set is then scanned exhaustively before a decision is made concerning the STM set items. The material from the LTM set could not be the actual LTM items, however, since this would predict identical scanning functions for the LTM and STM sets.

An alternative explanation of the data from Condition S suggests that *Ss* were able to differentiate between the LTM and STM set only when there was a single item in the LTM set. This interpretation is suggested by the data of Darley, Klatzky, and Atkinson (1972), which indicate that *Ss* are able to process items which have a high probability of being tested, independent of the remaining items on a list. In this study, when there was a single item in the LTM set, it was tested 25% of the time (50% positive probes, 50% LTM tests) a proportion of testing that might lead to this item being treated as a high-probability test item. This explanation is not supported, however, by the fact that a similar facilitation did not occur in Condition D.

INFLUENCE OF ACTIVE AND PASSIVE VOCALIZATION ON SHORT-TERM RECALL[1]

PHILLIP M. TELL[2] AND ALEXANDER M. FERGUSON

Florida Technological University

The Brown–Peterson distractor technique was used to investigate the effects of active and passive vocalization vs. silent visual presentation on recall at various retention intervals. Under active vocalization conditions, visually presented stimulus items were voiced aloud by *S*, and under passive vocalization conditions, these items were aurally presented by *E*. The findings indicated that both active and passive vocalization produced better recall than the silent presentation condition at retention intervals of up to 5 sec. Also, the active and passive vocalization conditions differed mainly at the longer retention intervals, with recall much higher under the passive vocalization condition. There were only minimal differences between active and passive vocalization at the short retention intervals.

There is currently much theoretical interest in the effects of various auditory and articulatory stimulus presentation conditions on short-term recall. In order to facilitate understanding, the present study will maintain Crowder's (1970) distinction between active and passive vocalization presentation conditions. Active vocalization refers to presentation conditions where the to-be-remembered stimulus items are voiced aloud by *S* as they are visually presented. Under passive vocalization conditions, *S* listens to *E* read each stimulus item as it is visually presented.

The findings of many experiments indicate that both auditory presentation of stimulus items by *E* (passive vocalization) and vocalization of these items by *S* (active vocalization) have significant advantages over silently read, visually presented items (Cooley & McNulty, 1967; Crowder, 1970; Murdock, 1966, 1967; Murray, 1965; Tell, 1971). This advantage of active vocalization over silent visual presentation has been demonstrated both with the Brown–Peterson distractor task (Brown, 1958; Peterson & Peterson, 1959) and the immediate memory task. It seems reasonable to assume that the same memory systems can be investigated through the use of the distractor task or the immediate memory task. Thus, recall performance at short retention intervals (distractor task) is assumed to reflect the same memory characteristics as recall at recency positions of the serial position curve. Likewise, it is assumed that recall after longer retention intervals should be comparable to the primacy positions of the serial position curve. When measured with the distractor task, active vocalization is superior to silent visual presentation mainly at retention intervals of less than 7 sec. (Tell & Voss, 1970). When measured with an immediate memory task, active vocalization is generally superior to silent visual presentation on the last few serial positions only (Conrad & Hull, 1968). The same general types of results also occur when passive vocalization is compared with silent visual presentation (Corballis, 1966; Crowder, 1970; Grant & McCormack, 1970). Thus, it strongly appears that the same information system can be investigated with both the distractor task and the immediate memory task.

Currently, the only available direct comparison of the effects of active and passive vocalization on immediate recall is by Crowder (1970). His most relevant finding in terms of the present discussion was that passive vocalization was superior to active vocalization for only the first few serial positions (primacy positions). Both of these conditions were superior to the silent visual presentation condition at the recency positions only.

It has previously been speculated that the auditory feedback that results from active vocalization is functionally equivalent as to the auditory input resulting from passive vocalization (Tell & Voss, 1970) as a source of information. Crowder's (1970) data indicate that this is clearly not the case. As Crowder speculates, active vocalization during presentation could interfere with effective rehearsal or encoding strategies compared to a passive condition, in which *S* is free to engage in whatever type of encoding activity is most effective. This may account for the apparent superiority of passive vocalization at the primacy positions.

The present study was designed to provide a finer analysis of the effects of active and passive vocalization vs. silent visual presentation on recall at various retention intervals through the use of the distractor technique. If recall performance at short retention intervals indeed reflects the operation of the same memory characteristics as does recall of recency items, then it would be predicted that both active and passive vocalization should be superior to silent visual presentation at these short retention intervals. Likewise, it is predicted that passive vocalization will be superior to active vocalization at longer retention intervals, which correspond informationally to the primacy positions of the serial position curve.

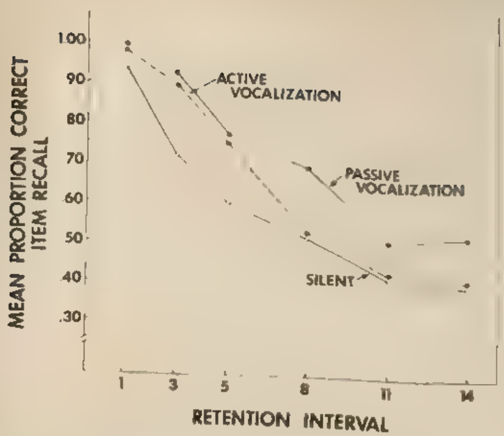

FIGURE 1. Mean proportion correct item recall as a function of presentation condition and retention interval.

Method. The *S*s were 90 undergraduates at Florida Technological University. All *S*s were tested individually and received course credit for participating in the experiment.

Twenty-eight consonant (C) trigrams were selected from the Witmer norms in Appendix B of Underwood and Schulz (1960) in such a way as to minimize association value and acoustic similarity. Repeated occurrences of any consonant were separated by at least 2 CCCs. Four of the 28 CCCs served as practice items and were not used in analysis of data or counterbalancing of conditions. The CCCs were photographed on 35-mm. film and mounted in slide holders. Blue gelatin filters mounted in slide holders marked the onset of each trial, and a series of 3 question marks served as the recall signals.

The slides were projected by means of a Kodak Carousel 800 projector. Series of 2-digit numbers for the interpolated task were filmed on 16-mm. motion picture film and projected with a Dunning Animatic film strip projector.

Both of these projectors were operated by tone pulses recorded on magnetic tape by the use of electromechanical programming equipment. One channel of a Sony Model 630 stereo tape recorder was used for this purpose. A Kodak Carousel programmer and sound synchronizer were used for both the recording and the playback of tones.

The second channel contained *E*'s recorded vocalizations of the CCCs, calibrated to coincide approximately with the visual display of the CCCs. This channel was turned on in the passive vocalization condition and was turned off under the silent and active vocalization conditions.

Using the Brown–Peterson distractor technique (Brown, 1958; Peterson & Peterson, 1959), *S*s attempted to retain CCCs while performing an interpolated task. The interpolated task involved the presentation of digit pairs at a rate of 1 sec/pair, and all *S*s were tested after 1, 3, 5, 8, 11, and 14 pairs of digits. The interpolated activity required *S* to verbally classify each member of the digi[t] as odd or even, from left to right.

Each *S* received 28 trials: the first 4 were [prac]tice and the rest were test trials. The o[rder of] trigram presentation was the same for all *S*s. [This] confounds practice completely with individua[l tri]grams, but balances practice against rete[ntion] interval.

The 90 *S*s were divided into 3 presentation [con]ditions. In the silent presentation condition, [ma]terials were presented visually and *S*s were request[ed] to silently read the trigrams to themselves. The active vocalization condition required *S*s to read the trigrams aloud while they were on the screen. Under the passive vocalization conditions, *S*s heard *E* read the trigrams aloud while they were presented on the screen. Thus, during the 24 scored trials in each of the 3 presentation conditions, a given *S* received 4 test trials at each of the 6 retention intervals.

A 6 × 6 Latin square was used to order the 6 retention intervals within the 24 test trials. [Each *S*] received an ordering of retention intervals d[eter]mined by 4 rows of the Latin square. Th[ree] separate samples composed of 4 rows each w[ere] used, so that each retention interval followed [all] other retention intervals an equal number of t[imes] and never followed itself. Within any presentation condition, 10 different *S*s received each of the 3 retention interval orders.

Briefly, a single trial proceeded in the following manner. A blue ready light illuminated the screen for 1 sec. Following this by .75 sec., a CCC was presented on the screen for .75 sec., during which time *S* either read it silently, spoke it aloud, or listened to it read by *E* over a speaker. After the presentation of each CCC, *S*s were tested at one of the 6 retention intervals (1, 3, 5, 8, 11 or 14 sec.). The interpolated activity was continually scored, and when necessary, *S*s were reminded to do as well as possible. Three question marks appeared after the last digit pair was removed from the screen. These remained on the screen for t[he] 10 sec. during which *S* attempted to recall the C[CC]. A rest interval of 10 sec. separated the trials.

Results and discussion. The data of each *S* were scored in terms of the number of consonants correctly recalled, regardless of whether they appeared in the correct intratrigram position. With low-association-value trigrams, it appears that the item score is the most meaningful and sensitive unit of analysis (Wickelgren, 1965). Results are not presented for ordered scores because they are in close agreement with item scores in all important respects.

An overall analysis of variance was performed on the recall scores. This analysis indicated that the 3 types of presentation conditions resulted in significantly different recall functions, F (2, 87) = 4.65, $p < .05$. As can be seen in Figure 1, recall performance for all groups decreased as a function of retention interval, F (5, 435) = 316.4, $p < .001$. It is apparent that the types of presentation conditions had different effects at the various retention intervals tested, F (10, 435) = 4.0,

$p < .01$. Both active and passive vocalization conditions are clearly superior to silent visual presentation at retention intervals of up to 5 sec. This might be assumed to result from the additional echoic information provided by the auditory input from these presentation conditions (Neisser, 1967). However, the initial differences between active vocalization and silent visual presentation disappear at the longer retention intervals (8, 11, and 14 sec.). It is also apparent that the passive vocalization condition provides higher recall than either of the other 2 presentation conditions at these longer retention intervals.

The present findings closely parallel those obtained with the immediate memory task (Crowder, 1970). First, both active and passive vocalization conditions produced better recall than the silent presentation condition at retention intervals of up to 5 sec. Second, the active and passive vocalization conditions differed mainly at the longer retention intervals. There are just minimal differences due to active or passive vocalization at the short retention intervals. The evidence strongly indicates that the same memory systems can be investigated using either supraspan memory units (immediate memory task) or subspan memory units (distractor task).

It appears that the requirement of active vocalization at presentation interferes with effective encoding operations. Active vocalization may demand more attention at presentation than does passive vocalization. The effect may not involve just the disruption of rehearsal strategies, but may instead lessen the selective attention capabilities that are necessary for effective encoding in memory. Thus, the advantages of passive vocalization are mainly at the longer retention intervals, when the information in echoic memory has dissipated. The pr[illegible]a clearly indicate that active and [illegible]ization conditions are not comparable [illegible]nput to the memory system when c[illegible]with silent visual presentation.

BELOW-ZERO CONDITIONED INHIBITION OF THE RABBIT'S NICTITATING MEMBRANE RESPONSE[1]

HORACE G. MARCHANT, III, AND JOHN W. MOORE[2]

University of Massachusetts

Albino rabbits received Pavlovian conditioned inhibition training of their nictitating membrane response to a light (positive conditioned stimulus, CS+) and the same light plus a pure tone (negative conditioned stimulus, CS−). Subsequent acquisition to the tone was retarded relative to naive and "sit" controls as well as groups receiving differential conditioning to noise (CS+) and light plus tone (CS−), and light (CS+) and light plus noise (CS−). The results were interpreted as demonstrating that conditioned inhibition training results in a CS with a negative (below-zero) value.

Although interest in Pavlovian conditioned inhibition has increased in recent years, there remain problems of interpretation of this phenomenon (Hearst, 1972). Conditioned inhibition is usually defined as a response tendency opposite that of excitation, where excitation is the increase in the strength of a conditioned response (CR) due to pairings of the conditioned stimulus (CS) and unconditioned stimulus (UCS). This definition of excitation implies that conditioned inhibition is a tendency to not respond resulting from presentation of the CS without reinforcement. The question of interpretation is whether failure to respond in this case may not be more parsimoniously conceptualized as resulting from a loss of excitation rather than from an active inhibitory process (cf. Brown & Jenkins, 1967).

The assumption that both excitatory and inhibitory forms of conditioning exist, separated by a point of zero-response strength, is a crucial feature of a number of learning theories, including familiar Hullian theories of discrimination learning (Spence, 1937). The theory of classical conditioning developed by Rescorla and Wagner also assumes that CR strength (V in their model) may take on either positive or negative value (cf. Wagner & Rescorla, 1972). The demonstration that conditioned inhibition results in a CS of negative value would seem to be of some importance for both of these theories.

The following 3 criteria should be satisfied in order to assert that a given training experience results in a CS with inhibitory properties: (*a*) a zero point must be established, (*b*) CR strength must lie below this point, and (*c*) this below-zero or negative effect must be the result of learning rather than some nonassociative factor such as an attention decrement. Marchant, Mis, and Moore (1972) investigated conditioned inhibition of the rabbit's nictitating membrane response (NMR) using Pavlov's procedure of reinforcing one stimulus (CS_1) while systematically nonreinforcing a compound consisting of CS_1 and another stimulus (CS_2). Although successful in demonstrating inhibitory summation and retardation (cf. Rescorla, 1969), this experiment failed to establish conditioned inhibition as a below-zero effect. One reason for this was that all *S*s were conditioned to CS_2, the potential inhibitor, prior to differential conditioning in an attempt to circumvent the development of latent inhibition to CS_2. Therefore, retardation was assessed in terms of rate of reacquisition following training rather than rate of initial acquisition. Secondly, control *S*s received prior conditioning to CS_2 followed by pseudoconditioned inhibition training in which each of the 2 trial types was paired with the UCS 50% of the time in a random sequence. Under these circumstances it seems unlikely that CS_2 in the control group defined a zero-reference point. Wagner and his associates have also investigated conditioned inhibition of the rabbit's eyeblink. These studies, while supporting the Rescorla and Wagner model, did not address the question whether conditioned inhibition is a below-zero effect (cf. Wagner & Rescorla, 1972).

The present experiment sought to establish conditioned inhibition of the rabbit's NMR as a below-zero effect by utilizing essentially the same training procedures employed by Marchant et al. (1972) but by comparing initial acquisition of the conditioned inhibitor with a reference group not subject to the complications mentioned above. Specifically, conditioning to CS_2 following inhibitory training was contrasted with a group which merely sat restrained in the conditioning chambers during the conditioned inhibition phase. Additional controls, not employed previously, were included to assess the role of a variety of potential artifacts contributing to retardation of acquisition to the inhibitory CS.

Method. The *S*s were 49 experimentally naive rabbits. Up to 4 *S*s were run simultaneously in ventilated soundproofed file drawers, and the details of recording the conditioned NMR have been described elsewhere (Marchant et al., 1972). The CSs were a 1,200-Hz. pure tone (T) of 86 db. SPL, 2 4.5-v. incandescent lights (L) behind milk

TABLE 1

Summary of Experimental Design

Group	Stage 1	Stage 2
Naive ($N = 7$)	—	T+
Sit ($N = 14$)	sit	T+
L+LT− ($N = 14$)	L+ LT−	T+
L+LN− ($N = 7$)	L+ LN−	T+
N+LT− ($N = 7$)	N+ LT−	T+

Note. Abbreviations: T = tone, L = light, N = noise burst, + = reinforced, − = nonreinforced.

white screens located in front of *S*, and an 86 db. SPL burst of white noise (N). The duration of each CS was a constant 550 msec. The UCS was a 2-ma. ac shock of 50-msec. duration delivered through stainless steel wound clips attached to the infraorbital region of the right eye. The intertrial interval was a constant 30 sec. and the interstimulus interval was 500 msec. throughout.

The experimental design is summarized in Table 1. One day prior to Stage 1 training (or, in the case of Group Naive, Stage 2 training), *S*s had their right NMs sutured and were habituated to restraint and the apparatus for a period of approximately 15 min. For *S*s in Group L + LT−, Stage 1 training consisted of 50 reinforced presentations of the L stimulus, unsystematically intermingled with 50 nonreinforced presentations of the simultaneous compound L plus T, in each daily session. This training was expected to produce an inhibitory T stimulus and was continued until the following criteria had been met: Between Sessions 6 and 12, if (*a*) percentage of CRs to CS− had first increased and then decreased over sessions and (*b*) percentage of CRs to CS+ was better than 80% and the percentage of CRs to CS− was less than 30%, then Stage 2 training began for that *S* midway through the next day's session. Group Naive did not participate in the experiment until Stage 2.

Group Sit served as a control for any possible effects of handling, suturing, sitting in restraint, experience with static apparatus cues, etc. In Stage 1, *S*s in this group were yoked to *S*s in Group L + LT− and were treated in an identical manner but without CS and UCS presentations. Group L + LN− was trained to the same criterion as Group L + LT−, but the discrimination was between L+ and (L + N)− as opposed to L+ and (L + T)− as in the Group L + LT−. Group L + LN− served as a control for experience with CSs, the UCS, conditioning and, more specifically, inhibitory training (i.e., inhibitory training per se may be sufficient to produce a deficit in acquisition of all stimuli). Group N + LT− was also run to the same criterion as Group L + LN−, and served as a control for experience with the LT− compound and generalization decrement in Stage 2.

The same nonsystematic order of CS+ and CS− trials in Stage 1 was used for Groups L + LT−, N + LT−, and L + LN−.

Stage 2 training for all groups began with 50 reinforced trials to T in the last half of the last session of Stage 1. This was followed by 100 trials 5 (±½) hr. later and 2 100-trial sessions the following day at approximately the same times as the previous day's sessions.

Results. All *S*s in Groups L + LT−, N + LT−, and L + LT− met the discrimination criteria in Stage 1 within the allotted 12 sessions. Acquisition to T in Stage 2 was assessed in terms of (*a*) trials to a criterion of 80% CRs over 3 consecutive blocks of 10 trials and (*b*) percentage of CRs over the initial 150 acquisition trials. Table 2 shows the mean of each measure of Stage 2 conditioning for each group.

Analysis of variance indicated significant ($p < .001$) differences among groups for both measures with $F(4, 44) = 19.56$, and $F(4, 44) = 13.91$, for trials to criterion and percentage of CRs, respectively.

Individual planned t tests based on the analyses of variance ($df = 44$) indicated that Group L + LT− was significantly slower to reach criterion than Group Sit, $t = 4.15$, $p < .001$. Group L + LT− was also slower to acquire than Group Naive, $t = 4.07$, $p < .001$. Description of the results of individual pair-wise contrasts among groups is confined to the trials to criterion measure since similar comparisons for percentage of CRs over the first 150 acquisition trials were significant at better than the .025 level.

Groups N+LT− and L+LN−, which did not differ significantly from each other, conditioned to T significantly more quickly than Group Sit, $t = 3.81$, $p < .001$, and $t = 3.94$, $p < .001$, respectively. Groups N+LT− and L+LN− also conditioned to T significantly more quickly than Group Naive, $t = 2.58$, $p < .01$, and $t = 2.70$, $p < .005$, respectively. Similar comparisons for percentage of CRs over the first 150 acquisition trials were also significant at better than the .005 level.

Discussion. The principal findings of this experiment were as follows. (*a*) Pavlovian conditioned inhibition training (L+LT−) resulted in retarded acquisition of the inhibitor (T) when compared with "sit" and naive controls. In this sense, conditioned inhibition produced a CS with negative or below-zero value as required by theo-

TABLE 2

Mean Trials to Criterion and Percentage of Conditioned Responses (CRs) in Stage 2

Group	Trials to criterion	Percentage of CRs
L + LT−	134.4	35.3
Sit	81.6	48.5
Naive	68.6	56.2
L + LN−	21.3	81.8
N + LT−	19.1	82.5

ries (Spence, 1937; Wagner & Rescorla, 1972) which assume the existence of active inhibitory as well as excitatory processes. (*b*) Differential conditioning in an N+LT− paradigm and conditioned inhibition training of a noise burst (L+LN−) both resulted in faster subsequent acquisition to T than in the sit and naive control groups.

The below-zero effect of conditioned inhibition training cannot be readily interpreted as resulting from an attention decrement since the criteria of differential conditioning imposed in Stage 1 of training assured attention to the conditional inhibitor right up to the onset of acquisition in Stage 2. If attention decrement were responsible for retardation of acquisition to T in Group L+LT−, retardation would have been observed in Group N+LT− as well. Failure to observe retardation to T in the latter group cannot be attributed to "overshadowing" of T by L since independent observations in our laboratory have established that T is the more effective CS in simple conditioning and hence the more "salient" of the 2 stimuli.

Repeated preexposure to the CS or UCS is known to retard conditioning of the rabbit's NMR (e.g., Mis & Moore, 1973). Groups N+LT− and L+LN− served as controls for these factors in the present experiment. The fact that conditioning to T in Groups L+LT− was substantially retarded relative to these 2 groups would seem to eliminate preexposure as the mechanism of retardation.

Failure to observe retardation to T in Groups N+LT− is consistent with the prediction of the Rescorla-Wagner model that inhibition develops as a consequence of nonreinforcement against a baseline or background of excitation (Wagner & Rescorla, 1972). In the present experiment, T in Group L+LT− satisfied this stipulation by virtue of the fact that nonreinforcement of T occurred in the presence of an excitatory CS, L, and retardation of acquisition to T was observed in this case. By contrast, L could not provide the excitatory component necessary for the development of inhibition to T in Group N+LT−.

Finally, Groups L+LN− acquired a CR to T more rapidly than any group other than N+LT−. Since both N and T are in the same modality, one might have expected inhibition to transfer from Stage 1 (N) to Stage 2 (T) and result in some retardation. That such transfer did not occur may have been due either to (*a*) excitatory transfer overcoming any inhibitory transfer present or (*b*) overshadowing of the L by the N so that Group L+LN− would be, in effect, a simple differential conditioning group. In the latter case no active inhibition would be produced due to the absence of an excitatory component.

THE APPARENT MAGNITUDE OF NUMBER SCALED BY RANDOM PRODUCTION [1]

WILLIAM P. BANKS [2] AND DAVID K. HILL [3]

Pomona College

A technique for generating a ratio scale for any psychophysical continuum by having *S*s generate subjectively random productions on that continuum is described and used to scale numerical magnitude, duration, and line length. The perceived magnitude of numbers grows as an increasingly decelerated function of their absolute magnitude, but it is approximately logarithmic from 10 to 1,000. The range of 1–500 is fitted well with a power function with an exponent of about $\frac{1}{3}$. Several experiments defend the position that the psychological scale of number is compressive and explore a number of possible artifacts in the random-production technique. Cross-modality matches between numbers, line lengths, and durations are predicted from the random-production scales derived for each of these dimensions. The predictions give power functions whose exponents are in some agreement with previous experimental estimates. Random-production scales for handgrip force, intensity of electric shocks, and subjective area are consistent with their magnitude-estimation scales, given that number has an exponent of $\frac{1}{3}$.

In magnitude-estimation experiments, *S* assigns numbers to stimuli according to some rule, and *E* must take him at his word on the rule he is using. Of course, there is no reason to assume that *S* is lying about his perceptions, but there is no way we can be sure that he has the same conception of the magnitude of the response numbers he is using that *E* (or arithmetic) does. Thus, if *S* calls a given stimulus "20," the magnitude-estimation technique assumes its subjective magnitude is twice that of the stimulus called "10." But *S*'s conception of the numerical magnitude could be such that a stimulus subjectively twice as great as the one called "10" would have to be called "30." In this case, the resulting scale, while replicable and capable of entering properly into cross-modality matches, would not reflect *sensory* magnitudes accurately.

The question of the form of the psychological scale of number is central to understanding the meaning of direct-scaling experiments; yet, while these experiments continue to proliferate and conclusions about sensory function continue to be drawn from them, no agreement on this important question has been reached. Perhaps the simplest and most convenient approach is to assume that the magnitude

[1] Experiments I–V were performed by the first author under a National Institute of Mental Health predoctoral training grant administered by Johns Hopkins University, U.S. Public Health Service Postdoctoral Grant 5T01-GM01207-05 at the Institute of Human Learning, University of California, Berkeley, and with the assistance of a Pomona College faculty research grant. Some of the writing was done with the support of a Pomona College summer research fellowship. Experiments VI–IX formed part of the second author's senior honors thesis at Pomona College and were supported by a Pomona College faculty research grant to the first author. Of the many who have made valuable suggestions on this work, P. Arabie, J. M. Myhre, E. A. C. Thomas, and W. S. Torgerson deserve particular thanks. The astute critical comments of R. D. Luce, L. E. Marks, and J. C. Stevens also contributed greatly to the paper, although the authors must apologize for not following their advice in every case.

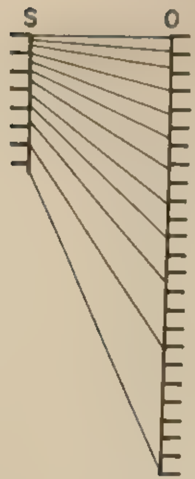

FIGURE 1. Psychophysical mapping between O, the observable continuum, and S, the continuum of subjective experience.

scale of number is linear. There is, however, evidence that it is not (cf. Atteneave, 1962; Curtis, 1970; Ekman & Hosman, 1965; Fairbank, 1969; Moyer & Landauer, 1967; Rule, 1969; Sekuler, Rubin, & Armstrong, 1971), and in any event it would be better to demonstrate its linearity before proceeding on the assumption that it is linear. (For evidence *for* linearity, see Dawson, 1971, and Goude, 1962.)

Previous attempts to scale the psychological number continuum have shown it to be compressive, but they are in some disagreement over the precise form of the function. Some seem to have shown that the scale is logarithmic (Moyer & Landauer, 1967), and others, that it is a power function (Curtis & Fox, 1969). These conflicting results reflect the difficulties intrinsic to the problem. Conventional direct-scaling techniques cannot be used in unmodified form because with them, one dimension must be scaled in terms of another. Whatever function is obtained will be a result of the input and output dimensions working together. Conventional indirect methods cannot be applied in unmodified form to scaling the numbers, either. One obvious difficulty is that there is no just noticeable difference for number (2 numbers are either equal or they are not), and thus there is no discrimination problem to exploit in constructing a scale. (However, for an ingeniously devised Thurstonian scale of number, see Rule, 1969).

This article reports experiments utilizing a new technique for studying how the magnitude of numbers is perceived. The technique can be used to scale any dimension *S* can control, and it is not limited to the numerical continuum. The technique is very simple: *S*s are asked to produce random quantities—in this case, numbers—as rapidly as possible, with no fixed upper limit, in no special order, and as randomly as possible. The assumption behind the random-number-production technique is that *S*s will display, by the form of the distribution they produce, their conception of numerical magnitude. It is as though *S*s refer to their internal "ruler"—presumably the same one that is used in magnitude estimation—and select numbers from this source in a nonsystematic fashion. Their sampling from this line is assumed to be rectilinear and random. By this reasoning, intervals will be represented in proportion to their psychological size. If, for example, the numbers 105 and 115 represent points that are about as far apart psychologically as 5 and 15, *S*s should generate, on the average, as many numbers in one of these intervals as in the other.

The assumption that *S*s sample rectilinearly from their subjective scale in the number-production task permits a powerful analysis of the results. If their sampling is in fact rectilinear, the expected value of the order statistic for the *n* random samples can give a ratio scale metric for the psychological continuum over which the samples were made, as the following considerations show.

In a random-production experiment on any continuum, *S* produces *n* subjective randomly selected quantities on that continuum. If the productions of each *S* are put in order from smallest to largest and an average of the productions at each ordinal position is taken across *S*s, then the resulting *n* averages estimate the expected values of the order statistics for those samples (Hogg, 1969). If sampling

on the continuum is uniform, that is if $f(x) = 1,\ 0 < x < 1$, then the probability density function of Y_k, the kth of the n order statistics on $0 < x < 1$, is

$$g_k(y) = \frac{n!}{(k-1)!(n-k)!} \cdot (y)^{k-1}(1-y)^{n-k}.$$

The expected value of Y_k can thus be calculated as follows:

$$E[Y_k] = \int_0^1 y g_k(y)dy$$

$$= \int_0^1 \frac{n!}{(k-1)!(n-k)!} \cdot y^k(1-y)^{n-k}dy$$

$$= \frac{n!}{(k-1)!(n-k)!} \cdot \frac{\Gamma(k+1)\cdot\Gamma(n-k+1)}{\Gamma(n+2)}$$

$$= \frac{n!}{(k-1)!(n-k)!} \cdot \frac{k!(n-k)!}{(n+1)!}$$

$$= k\frac{1}{n+1}.$$

Thus, the order statistics divide the 0–1 line into n equally spaced points with a unit difference of $1/(n+1)$. That is, the kth order statistic will be k units of size $1/(n+1)$ from the bottom. If the line extended from zero to N, the unit difference would then be $N/(n+1)$.

It will be assumed throughout this article that *Ss* map all continua, in the process of perceiving them, onto a "subjective" scale which, for the sake of convenience, will be represented as a line going from zero to one. Figure 1 illustrates this mapping. In the figure, the O scale represents the physical (observable) continuum, and the S scale represents the subjective mapping of this continuum. The mapping function, M(O), assumed in this figure is monotonic and compressive but, in general, it may not be compressive for all continua. In the case of numbers, "infinity" may be mapped on the subjective continuum; if it is, the subjective continuum, being finite, must become infinitely compressed at the top.

When *Ss* are asked to sample rectilinearly from a continuum, they must do this sampling on the S continuum, for this is all that is available to them. Thus, to the extent that *Ss* can obey the rectilinearity instructions, the order statistics derived from n random samples will determine n points on the S continuum, equally spaced with a unit proportional to $1/(n+1)$. The S values are not, of course, directly available, but the order statistics that result from a random-production experiment provide n values on the O continuum that correspond to n equally spaced values on the S continuum. The transformation of the O continuum that spaces the order statistics on O linearly is M(O), the psychophysical mapping function. This scale estimated by the order statistic is determined except for the origin and has a constant unit. It thus provides an interval scale of subjectively spaced O values if the O scale is interval or better. If a zero point can be located on the S scale that corresponds to a known point on the O scale [i.e., $M(O_0) = S_0$], then the order statistic gives a ratio scale of the S continuum.

Experiments I–III

These experiments illustrate the basic random-number-generation task as applied with some variations. The experiments are reported in chronological order and show some evolution in technique, but the findings are essentially the same in all 3.

Method

The *Ss* were asked to produce random whole numbers rapidly and with no upper limit. They were instructed not to produce long sequences of numbers in the same neighborhood and not to count or give more numbers in order than would be expected by chance. In Experiment I, instructions to this effect were given in an informal manner to 4 psychology graduate students at Johns Hopkins University. These *Ss* were friends of *E* but were kept ignorant of the intent of the experiment. Their first 26 responses were written down.

In Experiment II *Ss* were 30 male and female undergraduates at the University of California, Berkeley, who performed the task individually while waiting to serve in another, unrelated experiment. The *Ss* spoke their responses into a tape

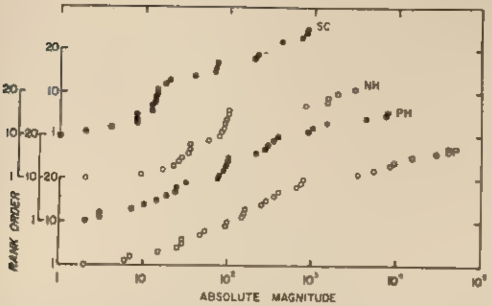

FIGURE 2. Ordinal magnitude vs. absolute magnitude for random numbers produced by 4 *S*s—SC, NH, PH, and BP: Experiment I. (Semilog coordinates.)

recorder after the following instructions were read to them:

> This is an experiment on how people think about numbers. What I would like you to do is give me any integers from one to the highest number you can imagine. I would like you to think of the numbers as going from one up, with no upper limit. Just skip about in the numbers and speak whatever number comes to mind into the microphone. Do it as quickly as you can and do not try to think about the numbers you are giving. Don't count or try to follow any kind of system. Try to make the numbers as random as you can. I will tell you when you have given me enough numbers.

Questions were answered (usually by referring to the instructions), the tape recorder was turned on, and *S* was asked to begin. Hesitancy on the part of some *S*s was overcome by repeating or paraphrasing parts of the instructions. Once *S* began giving numbers, *E* looked away and assumed a bland expression to avoid giving subtle hints about what was expected (cf., Greenspoon, 1955; Orne, 1962). The *S*s were, however, told to "be more random" or to observe no limits if they appeared to be counting or limiting themselves to numbers in a small interval, and they were urged to go faster if their rate of number production was less than 1 per 2 sec. or so. The *S*s were allowed to generate 30 numbers or more before being stopped. Numbers above 1 billion were discarded from analysis, and the first 25 acceptable numbers given were transcribed from the tape.

Experiment III was a replication of Experiment II with slightly different instructions. The *S*s were 20 male and female Pomona College undergraduates interviewed individually during breaks in an introductory psychology laboratory section. The instructions differed from those of Experiment II only in that *S*s were asked to pretend they were a "random-number-generating machine" and were asked to deliver the numbers "as if free associating." The *S*s gave about 30 responses, all of which were tape recorded. The first 15 responses under 10,000 were transcribed for analysis.

Results

The responses given by each *S* i[n] experiments were put in order befor[e] analysis was performed. Thus, i[f] sequence as generated was 3, 97, 29, it was put in order as 3, 8, 29, 97. (This is, of course, the first step in calculating the order statistics.) Numbers in the ordered sequence tend to increase exponentially in absolute magnitude as a function of ordinal position. For example, the geometric mean of the smallest number given by each *S* in Experiment II was 1.65, and the geometric mean of the largest (twenty-fifth in the order) was 3770, but the geometric mean of each *S*'s median number was 67.2. This dramatic increase in the size of the numbers with ordinal position can be seen in Figure 2, where the ordinal position of the numbers given by *S*s in Experiment I is plotted against the absolute size of the numbers.[4] The logarithmic abscissa in this figure reduces the increase of the numbers to an approximately linear one for each *S*. Two aspects of the functions of Figure 2 are of interest. First, the plots for each *S* show an overall logarithmic trend for most of their extent, but have regions of scalloping at various points. Second, the functions show some systematic departure from the logarithmic trend for numbers in the regi[on] below 10 or 15. Almost every *S* wh[o per]formed in the random-number-production task displayed these features in the numbers he gave.

[4] Intuition seems to demand that the x and y coordinates of Figure 2 be reversed so that size of an emitted number would be plotted as a function of rank order. Such a plotting would make the variable that can vary freely—size of number—the dependent variable, but this fact is not sufficient to make number the logically dependent variable. The relationship between size and rank (or between the magnitude and rank order of order statistics) resists logical division into independent and dependent variables. The arrangement of Figure 2 will be followed in subsequent figures because the function it shows is M(O). Interchanging coordinates would depict $M^{-1}(O)$ and might lead to some confusion.

The Averaging Problem

Each S's set of n random productions represents but 1 sample of the order statistics and consequently gives a noisy estimate of M(O). Averaging across Ss is clearly necessary for an accurate picture of the average M(O), but how to perform this averaging is a problem not easily resolved. The value of each of the productions obtained from any random-production experiment is necessarily on the O scale (see Figure 1). The "values" on the S scale are inaccessible, and the S continuum and its associated psychophysical function are, in fact, only intervening variables that serve to explain why subjectively equally spaced points on O are not equidistant in the units of O. In order to arrive at the best estimate of the order statistic, however, averaging of Ss' responses should take place on the S scale, because rectilinearity of sampling can hold only on the S continuum. Sampling is not rectilinear on the O scale, and the expected values of the order statistics cannot be estimated accurately by taking arithmetic means of untransformed O values. An obvious solution to the problem would be to transform the O values to numbers proportional to the S values, average these numbers, and then reconvert the averages to O values by the inverse transformation. Of course, for a precise estimate of the S_i that corresponds to each O_i, the transformation used must be M(O), and this is the unknown function to be estimated by the values of the order statistics.

Estimating order statistics with medians. Fortunately, there are a number of solutions to the averaging problem. The simplest is to take the median of the productions at each ordinal position. These are based on values on the O scale, but converting O to S by any monotonic M(O), taking medians of the S values, and then transforming the S medians back to O values by $M^{-1}(S)$ will result in O values very nearly the same as the simple median of the original O values. Thus, medians taken on the O scale can provide an estimate of the O values that correspond to the order statistics on S without requiring that any particular M(O) be assumed.

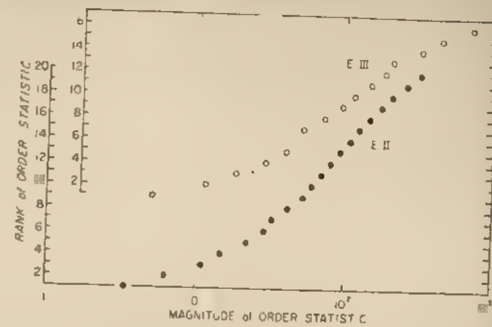

FIGURE 3. Rank of order statistic plotted against its magnitude estimated by the median of the constant-corrected numbers: Experiments II and III. (Semilog coordinates.)

The median has, however, a striking defect as a measure of central tendency in this situation. Unfortunately, with the present data, medians tend not to give an average scale but give rather the scale of the small number of "average" Ss whose productions tend to fall consistently in the middle range at each ordinal position. The medians can, however, be made much more representative of the average scale if individual differences in range and size of numbers are reduced by a correction procedure before medians are taken. An appropriate correction can allow all Ss to contribute equally to the median. Accordingly, each S's numbers in Experiments II and III were normalized by a multiplicative constant chosen so that the geometric mean of S's transformed numbers was equal to the overall geometric mean of numbers given in the experiment in which he performed. (This procedure is similar to the "modulus equalization" technique.) The constant correction was successful on at least 2 grounds: the standard deviation associated with each order statistic was reduced by approximately 20%, and nearly every S had a corrected number directly involved in the computation of one of the medians. A power transformation was also tried out as a method for normalizing the numbers, but the order statistics had standard deviations larger than those obtained with the constant transformation.

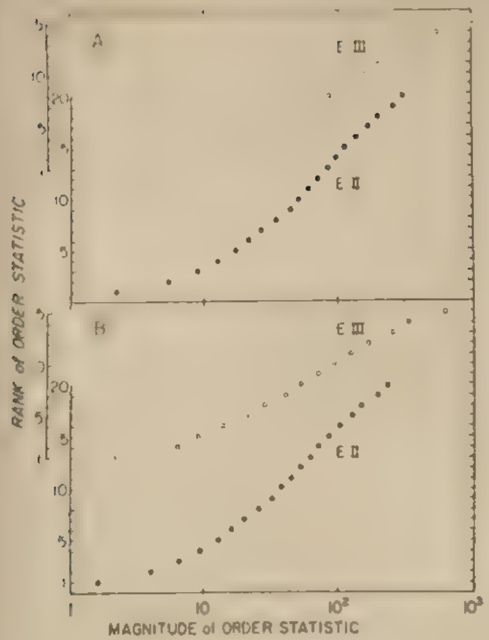

FIGURE 4. Rank vs. magnitude of order statistic for Experiments II and III. (In A the magnitude is estimated by the geometric mean of the constant-corrected numbers; in B, by the geometric mean of the untransformed numbers. Semilog coordinates.)

Figure 3 shows the relationship between the order statistics, estimated by medians of the constant-corrected numbers, and ordinal rank for Experiments II and III. The first 20 of the 25 order statistics of Experiment II and all 15 of Experiment III are shown. The general trends seen in Figure 2 show up strikingly in Figure 3. The functions are linear at the smaller numbers and show some acceleration in the semilog coordinates until a magnitude of about 12 is reached, where they become logarithmic until numbers near 1,000 are reached. Within this central range, the magnitude of the numbers from one ordinal position to the next increases by a very nearly constant percentage. For the highest numbers, the function becomes more compressed than a logarithmic function, something not seen in all the individual functions.

Estimating order statistics with geometric means. Still another averaging method is to estimate the order statistics with means of the corrected numbers at each ordinal position in the ordered output. The geometric mean seems the best one to use in this case, largely because the numbers found at each ordinal position are positively skewed, even in the corrected data. A further reason for using the geometric mean is that the functions of Figures 2 and 3 are approximately logarithmic, indicating that M(O) may be approximately logarithmic. If M(O) is a log function, taking geometric means of the O values is equivalent to taking arithmetic means on the S scale and transforming the means by $M^{-1}(O)$ to obtain estimates of values on O that correspond to the order statistics on S. If the M(O) for each *S* is a power function, geometric means will give an overall power function whose exponent is the arithmetic average of the exponents for the individual functions (Bruvold & Gaffey, 1965).

Figure 4A shows the relationship between the rank of the order statistic and the magnitude of the order statistic, estimated by the geometric means of the constant-corrected numbers for Experiments II and III. These functions show all the features of those in Figure 3, and they are somewhat smoother. In addition, they are very similar to the functions obtained by estimating the order statistics with the geometric means of the uncorrected data, as Figure 4B shows.

Cumulative Distributions of Numbers

The cumulative distribution of the numbers produced by *S*s is a concise summary of the data, although such a distribution does not bear a simple relationship to the order-statistic analysis. Table 1 shows the cumulative proportional distribution of numbers given in Experiments II and III. Table 2 shows the results when steps are taken to reduce individual differences in the numbers given. For this table, only the first 10 numbers given below 1,000 were taken from each *S*'s protocol. The numbers were then normalized by a multiplicative constant that equalized the geometric mean of *S*s' 10 numbers.

These distributions show that small numbers are more likely to be selected than large ones. Such a bias in the selection of numbers is to be expected from the compressive scales of number shown in Figures 3 and 4. As the subjective distance between arithmetically equidistant numbers decreases, the numbers *Ss* select will be spaced farther apart, and thus fewer numbers will be selected from an interval of a given width.

The cumulative distributions emphasize a hypothesis about the results that will be discussed later; viz., that *Ss* perceive numbers in a linear manner, but sample from them nonlinearly. This hypothesis runs counter to the hypothesis maintained here—that *Ss* sample rectilinearly from a nonlinear subjective representation of the numbers—but it is impossible to decide in favor of one or the other on the basis of random productions alone. Experiment IV was designed to decide between these hypotheses, and the results of other experiments below are relevant to the decision between them.

Discussion

Under the assumption that *Ss* generate random integers by selecting quantities uniformly from a psychological number space (the S continuum), the results of Experiments I-III indicate that this space is compressive: successive numbers must lie closer and closer together as they become larger. Figure 5 shows values on the O dimension corresponding to the order statistics on S that would be obtained by uniform sampling from the S scale with various M(O)s.

The function labeled L would result if the psychological distances between numbers were proportional to their logarithms. According to this distribution, the subjective ruler is calibrated in the same way as the C or D

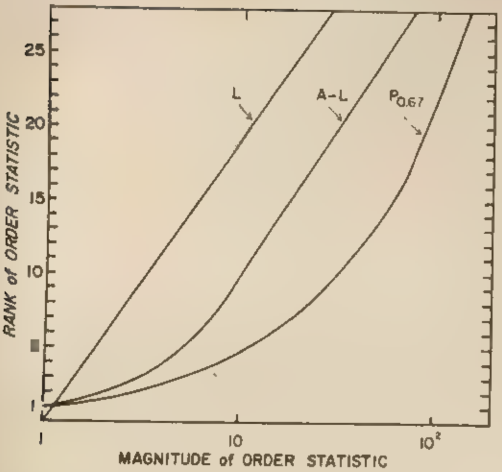

FIGURE 5. The rank vs. magnitude functions that would result for the order statistics if rectilinear samples were taken on a logarithmically compressed continuum (L), a partly logarithmic, partly linear continuum (A–L), and a continuum compressed according to a power law with an exponent of .67 ($P_{.67}$).

scale of a slide rule; that is, $M(O) = k \log O$. Numbers selected randomly from such a ruler and put in order will show an exponential increase with ordinal position, and the rank of the order statistics and the logarithm of their absolute size will be linearly related. The slope of the function is determined by the length of the ruler over which the sample is taken. The slope is not, however, at issue here. The point is that a logarithmic M(O) leads to a linear plot of the ordered samples in semilog coordinates, and numbers obtained from *Ss* in the number-generation task give such a plot for much of their range. That the obtained plots are not strictly linear in semilog coordinates is clear, and other assumptions about the psychological scale of number come closer to representing the full range of data.

The function labeled A–L in Figure 5 shows what happens if it is assumed that the psychological scale is linear for the numbers 1–10 and logarithmic thereafter. This assumption is not intuitively unreasonable, although it is mathematically cumbersome. We have a good understanding of the integers under 10 and of the relative distances among them, but above 10 or so the numbers become less distinct, and we are more willing to accept a percentage error of "rounding off" when quantities are expressed in terms of these numbers. If, in fact, we demand amount accuracy for small numbers but prefer percentage accuracy for larger numbers, a subjective scale of number like the one leading to the A–L function is implied.

A scale of numerical magnitude that has excellent empirical support is the power function (e.g., Curtis, 1970; Curtis & Fox, 1969). The $P_{.67}$ function in Figure 5 is based on a scale of number constructed according to a power function with an exponent of .67. For $P_{.67}$, $M(O) = k \cdot O^{.67}$. Numbers on this scale are spaced in such a way that their $\frac{2}{3}$ powers, if written next to them, would be linearly spaced. This power function results in order statistics that closely parallel the functions of Figures 3 and 4 for numbers below 500 or 1,000, but at the upper end of the range, the divergence of the empirical functions from a power function is great.

Fitting any function to the order statistics obtained from the number-production task is complicated by the flattening of the plots for numbers above 500 or 1,000. This deceleration would seem to indicate that the subjective scale of number becomes very compressed around 1,000 and is even more compressed for higher numbers. This apparent compression may simply result from a very poor understanding of large numbers on the part of *Ss*. The *Ss* tended, for example, to give numbers such as a billion, a trillion, and a zillion (or a quadrillion, etc.) with approximately equal frequency. It is likely that numbers of this size, and perhaps those as small as 1,000, are much less meaningful to *Ss* than smaller numbers, and they emitted the names of these numbers only in order to touch upon the vaguely understood realm of very large numbers in their output.

It is clear that numbers that are really only names and do not stand for magnitudes should be eliminated from consideration in attempts to discover the best M(O). Not only do the meaningless numbers put an unrealistic compression at the top of the scale but they also affect the function for lower numbers by entering into the averages that estimate many of the order statistics. In an attempt to eliminate the effect of large numbers on the estimate of M(O), the data of Experiments II and III were retabulated with numbers above 1,000 excluded. This procedure arbitrarily assumes that numbers become meaningless at about 1,000. The choice of 1,000 or any number is arbitrary because the lower limit of "meaninglessness" in numbers is difficult to define, and *Ss* probably differ widely in the range of numbers for which they have an intuitive understanding. Whether or not 1,000 marks the

limit of meaningful numbers, however, it is at the upper limit of numbers normally given by *S*s in magnitude-estimation experiments and thus, at the upper end of the subjective ruler that the order statistic is intended to calibrate.

Figure 6 shows the relationship between the order statistics estimated by the geometric mean of constant-corrected numbers and the ordinal rank of the statistics in Experiments II and III, when all numbers above 1,000 are eliminated from *S*s' output before the numbers are put in order for averaging. Only 10 order statistics were computed for this figure because the upper limit of 1,000 reduces the number of acceptable numbers that can be obtained from every *S*. Also plotted in Figure 6 is the function given by 5 male Johns Hopkins undergraduates who were asked, while waiting to serve in another experiment, to give random numbers, with the restriction of an upper limit of 1,000. They were allowed to emit 26 numbers, and all 26 were used. The order statistics were estimated by the geometric means of the untransformed numbers.

This figure is plotted in log–log coordinates to show that a power function describes the results. In log–log coordinates, a power function is a straight line whose slope is equal to the exponent of the power function. The functions of Experiments II and III in Figure 6 are fairly linear, although they have some curvature, especially at the upper end. Evidently, for at least some *S*s, 1,000 is well into the range of meaningless numbers. The linear portion of the curves is best described by a power function with an exponent of .60 for Experiment II and of .67 for Experiment III. The M(O) may, therefore, be a power function with an exponent around $\frac{2}{3}$. Interestingly, this value is close to being an average of the various exponents for number that Curtis and his colleagues (Curtis, 1970; Curtis & Fox, 1969) have found in fits of their 2-stage model to judgments of differences between psychophysical quantities. It is also very close to the exponent of .63 for number that Rule and Curtis (1973) found with nonmetric scaling. The fact of individual differences in output exponents (Curtis, Attneave, & Harrington, 1968) and task variables that may alter the output exponent (Poulton, 1968) indicates that the value of $\frac{2}{3}$ can be at best a first-order approximation to the exponent.

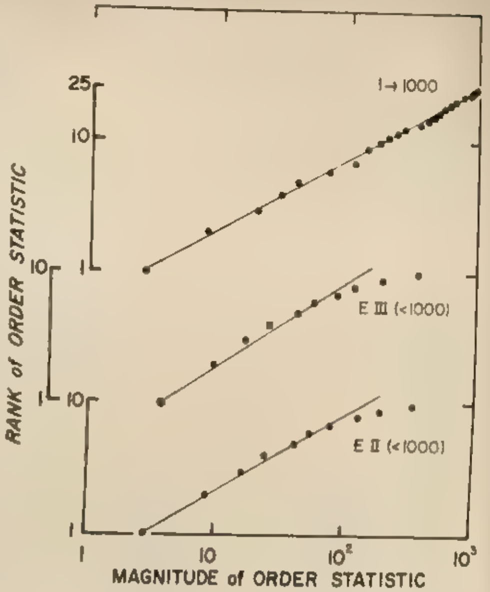

Figure 6. Rank vs. magnitude of order statistic for *S*s who generated integers with an upper limit of 1,000, labeled 1 → 1,000 and for *S*s of Experiments II and III when numbers above 1,000 were excluded, labeled E II (<1,000) and E III (<1,000), respectively. (Log–log coordinates.)

Experiments IV–VII

The results of the random-number-generating task have been taken as evidence for a psychological scale of number that is negatively accelerated. Two functions relating perceived size of number to absolute magnitude have been considered—a power function and a partly linear, partly logarithmic function (A–L). Both functions cover the scale up to about 1,000, where numbers may become meaningless, but this limit is above the upper limit of numbers commonly used in magnitude estimation.

While deciding between the power and A–L functions is a theoretically important task, determining that the obtained functions reflect the subjective scale of number and not some irrelevant factor in the number-generation task is a more immediate problem. There are a host of alternative explanations for the results, and the following experiments are directed at some of them.

Experiment IV tests the notion that the numerical continuum is subjectively linear and that nonuniform sampling results in the obtained functions. The method used allows linear sampling from a compressed "number line" to be distinguished from nonlinear sampling along a linear continuum.

Experiment V investigated the plausibility of a simple number-generation strategy that would lead to results of the sort obtained. Using this strategy, *S* would generate random single digits and decide, more or less randomly, whether to cut the string of digits at a 1-, 2-, 3-, or 4-digit or longer number. If each length of string were used equally often, about as many numbers would be produced among the units, tens, hundreds, and so on, and the ordered output functions would be approximately linear in semilog. In this experiment, *S*s were asked to give random numbers from the range ≥ 100. If *S*s were simply cutting digits into strings of random length for output, the interval 100–999, which contains numbers that are all of the same length, should be equally represented from end to end and should show a linear increase in magnitude as a function of ordinal position in the ordered output. This experiment also tests a "least effort" hypothesis of number generation. According to this hypothesis, *S*s find it easier and quicker to give small numbers. They therefore concentrate on the smaller ones, but throw in large numbers from time to time to satisfy the somewhat vague requirements of the task. Such a least effort strategy should produce a linear function over the range 100–999, since all these numbers are equally troublesome to produce.

Experiment VI investigated some effects of reinforcement and instructions on the distribution of numbers obtained in the random-number-generation task. Subtle cues from *E* can have a strong effect on behavior in a situation as unstructured as the number-generation task (Greenspoon, 1955; Orne, 1962), and it is possible that *E* was unconsciously cuing *S* to produce a distribution of the desired form. In Part 1 of this experiment, the effect of deliberately asking for larger or smaller numbers was determined. In Part 2, *S*s were presented with either an arithmetic or a geometric series (in random order) as a "good example" of a random series, and then produced their own set of numbers. If subtle cues have any effect on *S*s' number-generation behavior, these explicit instructions should have a strong effect.

Experiment VII tested the notion that, in generating their numbers, *S*s merely reflect the "spew" principle (Underwood & Schulz, 1960) by producing numbers in proportion to the frequency with which they encounter them in daily life. Small numbers are used more frequently than large ones in almost every application of numbers—from street addresses in *American Men of Science* to physical measurements (Benford, 1938; Raimi 1969)—and the decrease in usage of numbers is a logarithmic function of their size. This decrease, sometimes called Benford's law, is a sort of Zipf's (1949) law for numbers. In this experiment, *S*s were asked for random numbers with zero as the lower limit, and they produced fractional and decimal numbers in addition to integers. Fractions and decimals are probably less common in everyday occurrence and should appear less often than integers in the output if *S*s' numbers merely reflect their daily experience with numbers. Furthermore, if the scale for number is not changed when nonintegers are permitted, an explanation solely in terms of the spew principle is impossible because of the relatively low language frequency of any arbitrary noninteger.

Experiment IV

Method

The 20 *S*s who participated in Experiment III were used. After generating the random numbers in that experiment they were shown a graph like that of Figure 7A drawn on a $8\frac{1}{2} \times 11$ in. sheet. They were told that this picture expressed their instructions for the number-generation task: the abscissa represented the numerical continuum, and the horizontal line indicated that their sampling procedure gave every number an equal chance of being selected. (Every *S* but 1, a physics major who pointed out that only integers were sampled,

accepted this as an adequate description of what he did.) They were then told that they should use a new sampling rule and were shown a graph similar to Figure 7B and 7C. According to this new rule, *S*s were to sample numbers randomly, as before, but were to limit the range of numbers from which they sampled.

Every *S* generated numbers in 6 intervals defined in terms of figures like 7B and 7C drawn on $8\frac{1}{2} \times 11$ in. sheets. The intervals were of 3 widths, "narrow" (1.91 cm.), "medium" (3.82 cm.), and "wide" (7.64 cm.), and were placed with their midpoints at 1 of 2 positions on the 20-cm. abscissa (number line). One position for the intervals was described as being "among the smaller numbers" and was 7 cm. from the origin. The other was 14 cm. from the origin and was described as being "among the larger numbers." Thus, the instructions for generating numbers in, for example, the 3.82-cm. interval with its midpoint 14 cm. from the origin were, "Now I would like you to give me random numbers from an interval of *medium* width among the *larger* numbers." (The *S* was shown the drawing to illustrate the instructions and had it before him while giving numbers.) The instructions for all 6 width–position combinations were constructed according to this formula.

The *S*s often asked such questions as "How wide is 'wide'?" and were always answered with "That's completely up to you." Half of the *S*s first generated numbers from the 3 intervals placed at the smaller end of the line, then from the 3 intervals placed at the higher position. The other half generated larger numbers first, then smaller ones. At each position on the number line, all *S*s generated numbers first from the narrow interval, then from the medium-sized interval, and then from the widest one. Each *S* gave 10 numbers for each interval presented before going on to the next one.

Of course, neither the numerical span the intervals were to contain nor the magnitude of the midpoint of the intervals was specified in the instructions. This was the whole point of the experiment: *S*s themselves specified both the width and the midpoint of the intervals, and the question of interest was whether they felt an interval of a given width encompassed more numbers if it was placed at the high end of the number range than if it was placed at the low end. Since all *S*s were told that the abscissa was open ended (i.e., that it went to infinity off the page), any compression they assumed in the mapping of numbers on this line resulted from their own visualizations of the continuum and was not forced on them by the instructions.

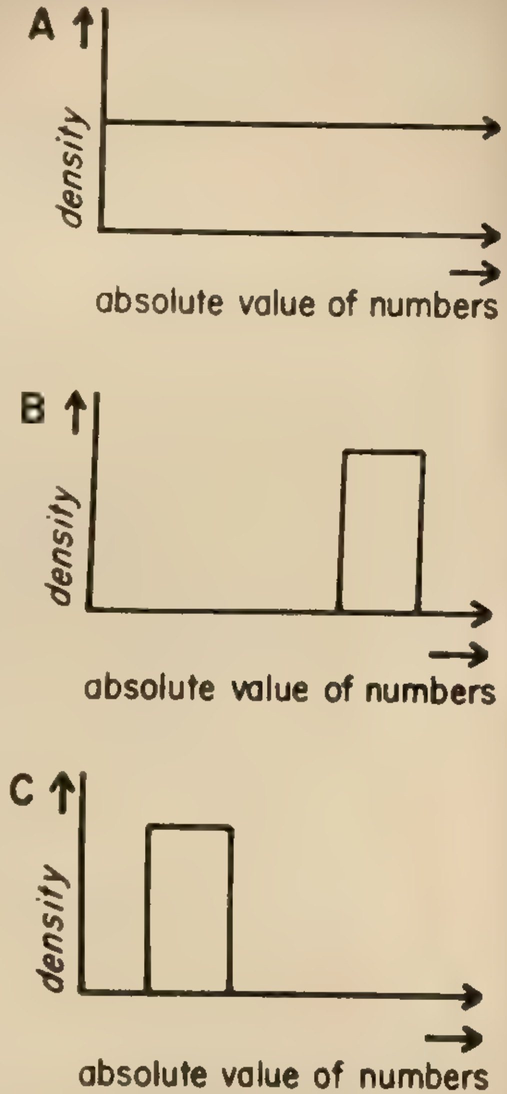

FIGURE 7. Examples of drawings used to instruct *S*s in Experiment IV.

Results

As Figure 8 shows, *S*s assumed that a given interval width, whether narrow, medium, or wide, spanned a greater numerical range when it was centered among the higher numbers than when it was centered among the smaller numbers. For example, when *S*s saw the wide interval placed among the smaller numbers, they assumed it spanned a range of 70, but among the larger numbers, the span jumped to 155. All but 3 of the 20 *S*s followed the trends shown in Figure 8, and no consistent differences between *S*s in the 2 counterbalancing conditions could be found.

An *S*s × Interval Width × Large vs. Small Numbers analysis of variance was performed on the logarithms of the range

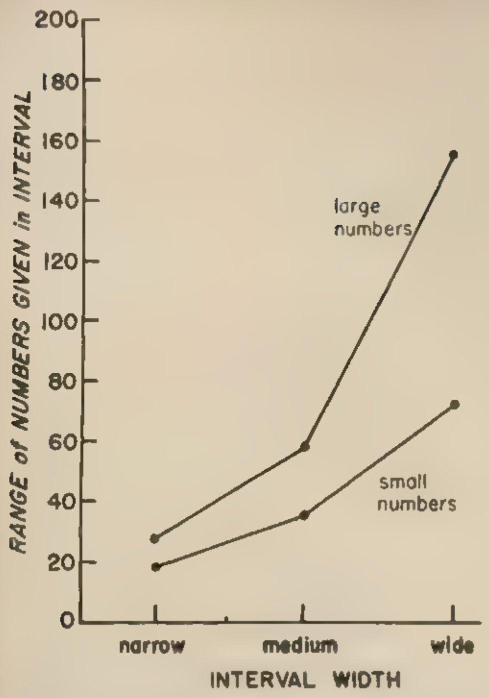

FIGURE 8. Results of Experiment IV. (Whether an interval was called narrow, medium, or wide, Ss assumed it spanned a greater numerical range when it was described as being "among the larger numbers.")

scores obtained from each *S*. The log transformation was used to reduce the differences in variability among the cells of the experiment. The large vs. small numbers variable was significant, $F\ (1, 19) = 12.7$, $p < .01$, when tested against its interaction with *S*s.

EXPERIMENT V

Method

Twelve *S*s from the population sampled in Experiment II were given the same number-generation task administered in that experiment, except that they were allowed to give only 20 numbers before being stopped. After giving the 20 random numbers, they were asked to do "the same thing again" but to maintain a lower bound of 100 instead of 1. The *S*s were urged to emit their numbers as quickly and as randomly as before, but were reminded that they should sample from "100 on up" this time. Approximately 25 numbers given by each *S* were tape recorded.

Results

Numbers over 20,000 were rejected from analysis, and the first 19 numbers given under this limit were transcribed from the tape. Three *S*s had to be rejected: 2 because they apparently interpreted the instructions as giving a lower limit of 1,000, and 1 because he gave only 12 numbers under the limit of 20,000 and would have reduced the range over which the data could be averaged. The responses of the remaining 9 *S*s were put in order, and geometric means were taken at each ordinal position. Figure 9 shows how the magnitude of the order statistics (geometric means of untransformed numbers) is related to their rank order. The results of both tasks performed by *S*s in this experiment are plotted so that the results found with the 2 ranges can be compared. The *S*s gave results similar to those of Experiments II and III when the lowest acceptable number was 1.0. Imposing a lower limit of 100 produced an almost perfectly logarithmic function, with no curvature at the lower limit. It would seem from this result that the curvature at the bottom of the other random-production scales of number is not an "end effect," but rather reflects the form of the subjective scale for small numbers.

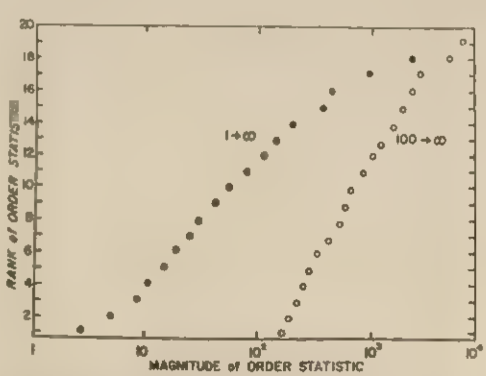

FIGURE 9. Rank vs. magnitude of order statistic when *S*s could give an unlimited range of integers ($1 \rightarrow \infty$) and when they could not give integers below 100 ($100 \rightarrow \infty$): Experiment V. (Semilog coordinates.)

Experiment VI, Part 1

Method

Experiments VI and VII were run concurrently with a total of 50 male and female *Ss*, all Pomona College undergraduates, none of whom had served in similar experiments previously. The *Ss* were assigned in rotation to the experiments in the order in which they arrived. The first 2 *Ss* were assigned to Experiment VI, Part 1, the next 2 *Ss* to Part 2, the next *S* to Experiment VII, and so on.

A total of 20 *Ss* served in Part 1 of Experiment VI. All *Ss* were initially given instructions for generating random numbers similar to those used in Experiment III, and all responses were tape recorded. After 10 responses had been given, half of the *Ss* were told that they were giving too many small numbers and should try to give more large ones. The other half were asked to give more small numbers because their numbers were too large. Some *Ss* were allowed to emit more than 10 numbers before the biasing instructions were given because they were in the process of giving a series of large (or small) numbers at the tenth item. The *Ss* in the *larger* biasing condition had to give at least 1 response under 10,000 after the tenth response before the biasing instructions were given, and *Ss* in the *smaller* condition had to give at least 1 response over 30 after the tenth before instructions were given.

Results

Figure 10A shows the order statistics (geometric means of the constant-corrected numbers) at each ordinal position before biasing instructions by *Ss* in the *larger* and *smaller* biasing conditions, respectively. In Figure 10B, the results of the bias toward larger and smaller numbers, respectively, are seen. The instructions in both cases had the intended effect of raising or lowering the overall range of numbers emitted, but the general form of the function seems little altered by the instructions. Both groups show curvature near the bottom and top of the range, with a logarithmic section in the middle, but *larger* instructions led to a more compressed scale than *smaller* instructions, especially at the top of the range. To a poor first approximation, the *larger* order statistics equal the squares of the *smaller* order statistics of the same rank.

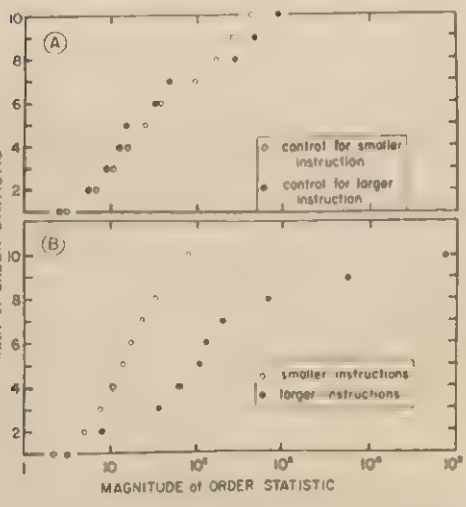

FIGURE 10. Rank vs. magnitude of order statistic before biasing instructions were given (A) and after *Ss* were told to give more small numbers (open circles) and more large numbers (filled circles) (B): Experiment VI, Part 1. (Semilog coordinates.)

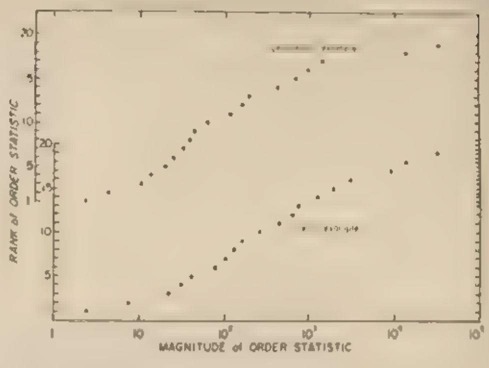

FIGURE 11. Rank vs. magnitude of order statistic for *Ss* who had heard a geometric "good example" of random numbers and for *Ss* who heard a linear "good example": Experiment VI, Part 2. (Semilog coordinates.)

Experiment VI, Part 2

Method

Twenty Pomona College undergraduates served as *Ss* in this experiment. All were given random-number-generation instructions. The *E* then played a tape-recorded series of integers, with the explanation that the series was a "good example" of what was expected of them. Two taped series were used. One contained 20 numbers in a linear series extending in equal steps from 1 to 130,000. The linear series was presented in random order, with small quantities added to or subtracted from each member to conceal the orderliness of the numbers. The other contained 20 numbers from a geometric series extending from 1 to 40,000. (The difference in the upper limits of the 2 series is the result of an error discovered too late. The effect is that the geometric

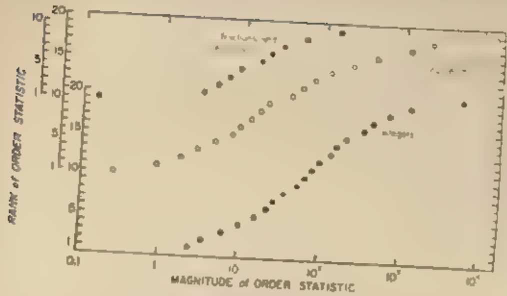

FIGURE 12. Rank vs. magnitude of order statistic when only integers could be produced and when the same *Ss* were later allowed to give fractions and decimals in addition to integers: Experiment XII. (Function for the fractions and decimals alone is also shown. Semilog coordinates.)

series is missing 3 or 4 members at its upper end.) The geometric series was also presented in random order, after small quantities were added to or subtracted from each member. Ten *Ss* had the arithmetic random series played to them, and 10 *Ss* heard the randomized geometric series. After hearing the series appropriate to his condition, each *S* dictated 20 numbers into the tape recorder.

Results

Figure 11 gives the order statistics (geometric means of constant-corrected numbers) at each ordinal position for both conditions. The random series derived from an arithmetic progression implies a subjective ruler graduated linearly, but it seemed to induce number-generation behavior consistent with the same compressed subjective ruler seen in Experiments I–III. The geometric random-number example is consistent with a subjective ruler graduated logarithmically. The numbers *Ss* produce after hearing this example imply a slightly more compressed psychological scale of number than do the numbers given by *Ss* who heard the arithmetic example, but this difference may simply be the result of the different ranges existing in the 2 examples. For most of its extent, however, the subjective scale derived from numbers given after either example of a good series is of the same form as that found in the other random-number-generation tasks.

EXPERIMENT VII

Method

In this experiment 10 *Ss*, all Pomona College undergraduates, had random-number-generation instructions read to them and sponses which were tape recorded asked to do "the same thing" aga that this time they could give frac and numbers of any size (above zero and fractional parts in addition to wh All responses were tape recorded, *Ss* to give 20 numbers, and all respons scribed from the tape and put in order

Results

Figure 12 shows the relation of the rank and the absolute size of the order statistic before and after the instructions allowing fractions were given. The function covers a wider range when fractions are allowed, but the form of the psychological scale of number implied is little alter Figure 12 is a plot of the ord based *only* on the nonintegers though 67% of the numbers nonintegers, 2 *Ss* gave only a few fractions and decimals and could not be counted in the curve for fractions and decimals only. Of the remaining 8 *Ss*, 2 *Ss* gave only 10 nonintegral numbers, and the resulting function therefore gives the results for only 10 order statistics for the 8 *Ss*. The functions in Figure 12 show that the M(O) for numbers does not depend critically on the use of integers. Furthermore, the function for nonintegers alone is very similar in form to that for integers.

Discussion: Experiments IV–VII

Experiment VII eliminates several interpretations of the results of Experiments I–III based on the spew principle. It cannot be maintained that *Ss* merely reflected their frequency of experience with numbers in the numbers they gave. Integers are probably more frequent in everyday life than with decimal parts, yet whole numbers were outnumbered 2 to 1 by fractional numbers in the responses when fractions were allowed. Except for a few common decimal numb such as 3.1416 and 1.414, and the fractions ½ and ¼, the fractional and decimal numbers *Ss* gave seemed very capricious, arbitrary, and uncommon; yet the psychological scale of number derived from only the fractions given by *Ss* is virtually the same as that found when only integers are allowed.

A modified form of the spew principle could be considered, according to which *Ss* feel

there are somehow "more" small numbers—whether small integers or small fractions. This version of the law reduces to the assumption that *S*s sample nonlinearly from a linear numerical continuum. Experiment IV shows, however, that *S*s assume that a given interval, whether narrow, medium, or wide, must span a greater numerical range as its mean increases. Such an assumption would not be made if the numerical continuum were psychologically linear.

Still another line of reasoning would have it that the numbers *S*s generate simply obey Benford's "law of first digits" (Benford, 1938; Raimi, 1969). Benford's law is a generalization based on the analysis of numbers found in a great many scientific and statistical tables. According to this law, the probability that a randomly selected number begins with a digit D is log (D + 1) − log D.

If *S*s simply use or obey this law in generating their numbers, the derived subjective scale for any decade interval will be logarithmic. If each decade interval from the units to, say, the ten thousands is sampled equally often by *S*s, then the subjective scale derived from numbers generated in the entire range of 1–99,999 will be logarithmic. While the obtained numbers are not perfectly consistent with a logarithmic subjective scale and are perhaps better described with a power law, the law of first digits comes very close to providing an explanation of the data.

A test of the first-digits artifact can be performed by examining the relative frequencies of numbers in a range wherein all begin with the same digit. If this artifact were solely responsible for the obtained results, the numbers given in any such range should be evenly distributed. Table 3 shows how numbers are distributed in the ranges 10–19 and 100–199 for Experiments II and III. All numbers given by all *S*s were included in the count, not just the first 25 or 15 used for the order statistics. Both cumulative distributions deviate significantly from linearity according to the Kolmogorov–Smirnov 1-sample test (Siegel, 1956).

In fairness to Benford (1938) it should be said that he felt that his law was really a reflection of a more general law of nature. Nature, it seems, counts exponentially or, in the terms of this study, generates quantities that are spaced linearly on a logarithmic scale, not a yardstick. Thus, the law of first digits is only 1 consequence of this law of nature, and numbers within any interval examined should be spaced with progressive compression of the scale toward the top. If this more general law is applied to behavior in the number-generation task, however, it reduces to the same assumption being made here and cannot be construed as an explanation in terms of an artifact. The *S*s agree with nature, so to speak, in using a negatively accelerated ruler to measure things. The subjective ruler probably became graduated as it is by *S*s' experience with quantities, but it cannot be argued that the effects of this experience appear in *S*s' number-generation behavior in unmediated form. The *S*s do not simply produce numbers with frequencies proportional to their experience with them, nor do they sample with a bias toward small numbers from a linear continuum. Rather, it seems that they have a nonlinear analog conception of numbers from which they sample as linearly as they can.

The other artifacts considered in Experiments IV–VII are more easily dismissed. Experiment VI showed that subtle reinforcements provided by *E* (Greenspoon, 1955) or, to phrase it differently, the "demand characteristics" of the task (Orne, 1962) can influence the range of numbers over which *S*

samples in generating his output and the overall compression of the scale, but they do not radically alter any conclusions about the form of the scale. Experiment V controlled for the possibility that *S*s simply produce random lengths of digit strings. This strategy could produce the results obtained if *S*s generated a roughly equal number of 1-, 2-, 3-, and 4-digit numbers. Such a strategy would, however, produce a linear psychological scale for the range 100–999, and the results of Experiment V show this not to be the case. (The distributions in Table 3 reinforce this conclusion.) Experiment V also renders untenable an explanation of the results in terms of a least effort strategy.

Individual Differences in Number Production

Since the functions for numbers reported here were obtained by averaging over *S*s, it is important to determine that individual differences in number production do not somehow conspire consistently, through the evils of averaging, to produce a group function that has little relevance to the number-generation behavior of individual *S*s. Two approaches to individual differences are reported below.

Individual scales for 12 subjects. The procedure of averaging over *S*s was used because the productions given by individual *S*s seemed noisy. It is possible, however, to achieve fairly smooth functions for individual *S*s by taking repeated observations and averaging within *S*s. To obtain these functions, 12 male and female University of Oregon students were interviewed individually each day for 5 days in a row. On each day they dictated 20–30 numbers into a tape recorder under standard number-production instructions. The first 10 numbers under 1,000 given on each day by each *S* were transcribed and put in order. Order statistics for each *S*, averaged over the 5 days, were estimated with geometric means.

Table 4 presents the goodness-of-fit measure r^2, for each *S* for the logarithmic and power M(O) functions for number. The table also lists the exponents for each *S* for the power function. Because the overall scale derived from this experiment showed the extra compression that may indicate meaningless numbers at the top end, the fitting procedure was repeated for only the first 8 order statistics for each *S*, and the results of these fits are also reported in Table 4.

It seems clear from Table 4 that either a log or a power function provides an excellent approximation to the subjective scale of number. Both account for an average of over 95% of the variance in the individual scales. Deciding between the 2 functions is, however, still difficult. When all 10 points on the scale are considered, the log function gives a better fit than the power function in 7 of the 12 cases, but the power function does better in 8 of 12 cases for the first 8 points—the points that fall on the part of the range most used in magnitude estimation.

The variability in the exponents compares favorably with the variability found in exponents of power functions fit to individual *S*s' magnitude-estimation scales. The standard deviation of about .14 is somewhat less than that found by Stevens and Guirao (1964) in a study of individual loudness functions for 11 *S*s, but it is larger than the standard deviations for brightness exponents Marks and Stevens (1966) obtained in a series of 4 experiments. It is also less than the variability found by Jones and Marcus (1961) and Bruvold and Gaffey (1965). The range from smallest to largest exponent is not an ideal measure of variability, but for some studies it is the only one available for comparison. The present ratio of about 2:1 between largest and smallest is about the same as or less than ranges found

in a number of studies reviewed by Marks and Stevens, less than the ranges found by Stevens and Guirao, and less than the ranges found by Stevens and Mack (1959), as reported by Stevens (1961a). It is greater than ranges found by Marks and Stevens and by Bruvold and Gaffey.

Individual scales from Experiment II. In a further attempt to assess the generality of the group M(O) function for individual *S*s, power and logarithmic functions were fit to the data given by each *S* in Experiment II. Fitting was done only on the numbers under 190 in order to reduce as much as possible the effect of meaningless numbers on the individual scales. Since about 70% of the numbers given and 18 of the 20 order statistics reported fall in this range, this upper limit should not distort the relationship between group and individual scales very much, at least not for the more important region.

The individual functions were quite well fit by a 2-parameter power function, $Y = AX^E$. The smallest goodness-of-fit measure was .86 (only 4 of the 30 r^2 values were below.90), and the mean was .938. A 2-parameter logarithmic function, $Y = A + B \log X$, also fit the data well, but not as well as the power function. The mean r^2 for the log function was .893, and the log function was superior to the power function for only 8 of the 30 *S*s. The goodness-of-fit measure for the log function is significantly worse than for the power function at the .01 level, $t\ (29) = 3.28$.

The mean of the power function exponents was .646, a value close to that of approximately $\frac{2}{3}$ suggested here for the power function M(O), and also close to the mean exponents reported in Table 4. There was also a high degree of uniformity among *S*s in their exponents. The standard deviation of the exponents was .105, and the range was .444–.964. The standard deviation is about the size to be expected in individual fits of power functions to magnitude-estimation data. Also, the ratio of slightly more than 2 to 1 between the largest and smallest exponents is within the range one would expect if individual power functions were fit to the magnitude-estimation scales given by 30 different *S*s.

The results of the individual curve fittings indicate that power functions fit individual number scales about as well as they fit individual magnitude-estimation scales. It therefore seems reasonable to consider the group average scale for number to have the same logical status as the group scale obtained in a magnitude-estimation experiment. The analysis of individual differences in scales derived by Bruvold and Gaffey (1965) seems as appropriate for the present number scales as it is for magnitude estimation. According to this analysis, the mean of the individual power function parameters equals the parameters fit to the data averaged over *S*s.

Experiments VIII and IX: Scaling Line Length and Duration by Random Productions

The random-production technique is not limited in principle to numbers. It can be used on any dimension whose quantities *S* can produce at will. The following experiments use this technique to scale 2 dimensions, line length and duration, which admit of easy random production. Although random-production scales for continua other than number are of interest in themselves, the present reason for generating these scales is to use them in a model, discussed below, to predict magnitude-estimation scales for psychophysical continua from their random-production scales.

Method

Random line lengths and random durations were produced in Experiments VIII and IX, respectively. Ten Pomona undergraduates served individually as *S*s in these experiments, half assigned to Experiment VIII first and then Experiment IX, and half assigned in the reverse order. Instructions were essentially the same as in Experiment III except that reference was made to random line lengths and periods of time instead of to numbers.

For Experiment VIII, *S*s were given a pencil and a roll of 5-cm.-wide adding-machine paper on a .75 × 1.5 m. desk. They were told to think of line length as a continuum extending from a point to the longest line they could conceive of and were asked to draw lines that represented randomly selected lengths on this continuum. They drew their lines from the loose end of the paper toward the roll and were allowed to unroll the paper as they needed more. They were not allowed, however, to hold the pencil down and pull the paper by beneath it. Pilot *S*s who used this strategy soon fell into frantic paper pulling, and it was decided they did not have much feeling for the line lengths they produced. After *S* had finished drawing each random line, the paper was unrolled about 20 cm. and he was asked to produce another line. All *S*s drew 20 random lines.

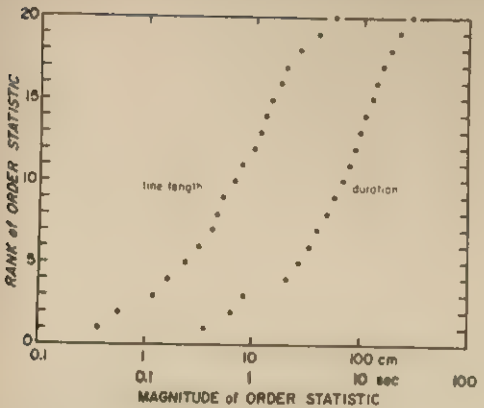

FIGURE 13. Rank vs. magnitude of order statistic for random productions of line lengths and durations: Experiments VIII and IX. (Semilog coordinates.)

In Experiment IX, *Ss* were given a microswitch that caused a Standard Electric Centisecond timer (out of *Ss'* sight) to accumulate time when it was depressed. They were told to think of durations as falling on a continuum extending from those of infinitesimal length to those as long as they could conceive of. They were asked to produce random durations from this continuum by holding the microswitch down for random periods. When *S* had completed a random duration, *E* recorded the timer reading to the nearest 1/100 sec., reset the timer, and asked for another random duration. All *Ss* produced 20 random durations.

Results and Discussion

Figure 13 shows the rank order that corresponds to each of the order statistics for both line length and duration. The functions for the 2 continua are quite similar, both being compressed and having a form that is in fact similar to that found with random productions of numbers. It is interesting that a compressed subjective scale for length is consistent with judgments and productions of sums of lines (Kreuger, 1970), even though judgments of length are linear (Stevens & Galanter, 1957). Equivalent evidence for a compressed duration scale does not seem to exist.

Randomly produced numbers have a considerably greater range than random line lengths or durations. The value of the order statistic in free number production often spans 5 log units, but the order statistics for both line length and durat[illegible] fit comfortably within 3 log units. Ma[illegible] mum quantities given by individual [illegible] also reflect this difference: the large[illegible] numbers were often in the billions or highe[illegible] but the longest random line drawn was [illegible] cm. and the longest duration produced w[illegible] just over 2 min. It is possible that [illegible] in these random production tasks feel, [illegible] they do not feel when generating numbe[illegible] that they should limit themselves to fai[illegible] small quantities. It also may be that va[illegible] magnitudes are easier said than done. [illegible] any event, the following analysis shows tha[illegible] the scales derived from the random-pro[illegible] duction tasks are not inconsistent wit[illegible] behavior seen in magnitude-estimatio[illegible] experiments.

Simulation of Magnitude Estimation and Cross-Modality Matching

A magnitude-estimation task has been characterized as one in which *S* matches numbers to the perceived size of his sensation according to a rule. If the random-production scales derived for number, line length, and duration reflect the perceived magnitudes of these dimensions, then the scales specify the rule *S* uses for matching. Magnitude-estimation behavior can thus be simulated by artificially matching numbers

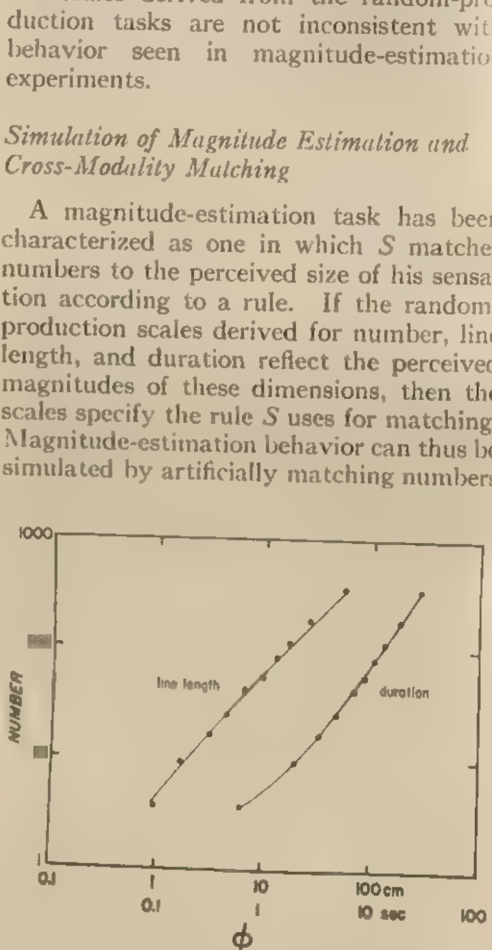

FIGURE 14. Simulated psychophysical function for the match between number and line length and between number and duration, using data from Experiments III, VIII, and IX. (Log log coordinates.)

to quantities on the estimated dimension in such a way that the subjective magnitudes of the numbers are paired with equivalent subjective quantities on the dimension. Since the order statistics are assumed to be equally spaced on the S dimension, the order statistic of Rank N on one dimension should be matched with the order statistic of the same rank on the other dimension to create the x–y pair that simulates a single magnitude estimation.

Figure 14 shows the scales that result when numbers are matched to equivalent subjective quantities of length and duration according to the random-production scales. The numbers used in these matches are from the scale of Experiment III when numbers above 1,000 were omitted (see Figure 6 and associated discussion), and the lengths and durations are from the scales of Experiments VIII and IX. Because only 10 order statistics were available for the scale of number used for the matches and 20 had been taken for duration and line length, order statistics of Rank N for number were matched to order statistics of Rank 2N for length and duration. When the random-production scale for the full set of numbers produced in Experiment III is used, functions similar to those of Figure 14 emerge, but they show acceleration at the upper end. Presumably, this acceleration results from the distorted scale for the very large numbers.

The linearity of the functions of Figure 14 in log–log coordinates indicates that power functions describe them well. The curvature in these functions occurs near the lower end and might be removed by a threshold correction. In this situation, however, the curvature probably means that the matching procedure does not line up the 2 continua in exactly the same way *S*s doing magnitude estimation would. The slope of the linear portion of the simulated apparent length function is close to 1.0, and that for the duration function is about 1.3. The simulated apparent length scale is thus quite close to that found by magnitude estimation, but the duration function is somewhat steeper than the 1.1 slope found in magnitude estimation (Stevens & Galanter, 1957). This difference between obtained and predicted slopes for duration may result from an artificial compression of the time dimension in random productions—even 1 min. of holding the button down seems like a very long time—but it may also be a result of the fact that there is no regression effect to lower slope in the simulated matches (Stevens & Greenbaum, 1966).

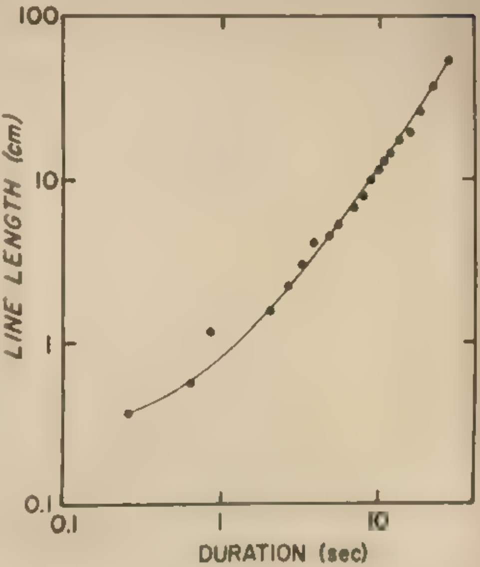

FIGURE 15. Simulated cross-modality match between line length and duration. (Log log coordinates.)

The random-production scales for line length and duration also allow the cross-modality match (Stevens, Mack, & Stevens, 1960; Stevens, 1959) for these dimensions to be simulated. Figure 15 shows the simulated result of a task where line lengths are drawn to match the apparent length of periods of time. For this simulation, order statistics of Rank N for length were paired with order statistics of Rank N for duration, and 20 simulated length–duration matches were thereby made. The function these simulated matches trace out is evidently well fit by a power function, as is shown by its near linearity in log–log coordinates. The curvature near the bottom seems to indicate a needed threshold correction, but again it may mean that match-

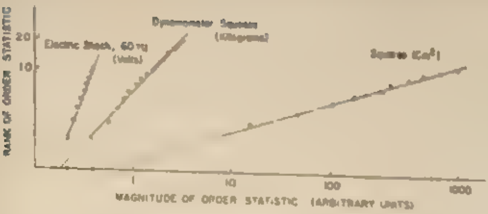

FIGURE 16. Random-production scales for subjective intensity of electric shock, force of handgrip squeeze, and areal extent, all arbitrarily placed on the X axis. (Log–log coordinates.)

ing behavior is not perfectly simulated. The linear portion of this function has a slope of about 1.4. This slope is somewhat steeper than it should be and may be too steep for a number of reasons, including the lack of a regression effect.

Random productions for other continua. Random-production scales have been obtained for subjective force of handgrip squeeze, subjective intensity of a 60-Hz. electric shock, and subjective areal extent (Banks, 1973). Figure 16 shows these scales with threshold corrections of 7 kg. for the handgrip scale and .1 cm.² for the area scale. The technique used to obtain these scales was very similar to that used for the length and duration scales presented in Figure 13. The *Ss* used a hand dynamometer to produce the handgrip squeezes, and a variable transformer, connected through a step-down transformer to saltwater finger electrodes, to produce random shocks. Areas were produced by freehand drawing of squares on unlined $8\frac{1}{2} \times 11$ in. paper.

A power function provides an excellent fit to each of these scales, accounting for over 98% of the variance of the means in every case. The exponents for the handgrip, shock, and area scales are 1.1, 2.5, and .30, respectively. These exponents are smaller than magnitude-estimation exponents for the same continua, but their small size is not consistent with a least effort (or least *pain*, in the case of shock) hypothesis of random-production behavior. First, the shock scale (which should be most compressed by such a hypothesis), is the most accelerated one, and the handgrip scale is the next most accelerated, while the area scale (whose large quanti[ties] are, if anything, easier to produce th[an] small quantities) is the most compress[ed]. Thus, *Ss* chose to give themselves more b[ig] than little shocks and more hard than eas[y] handgrip squeezes, but they drew mor[e] little squares than big ones.

Another version of the least effort hypothesis, that *Ss* produce a compressed version of the "true" psychophysical scale as given by the magnitude-estimation function, is also inconsistent with the results. The shock scale (which should be the most relatively compressed by this account) underestimates the magnitude-estimation exponent the least, the handgrip scale the next least, and the area scale the most.

It seems best to view random production as a scaling technique, especially since the least effort hypothesis of the results is disconfirmed and nothing plausible seems available to replace it. The fact that the random-production scales for shock, handgrip, and area are consistent with magnitude-estimation scales under the assumption of a nonlinear scale for number is discussed in the following section.

GENERAL DISCUSSION

Implications of scales of number. Although previous research (e.g., Curtis, 1970; Rule, 1969; Rule & Curtis, 1973) and the present evidence point to a nonlinear psychophysical function for number, the question of precisely what this function is has not been answered. The evidence seems to indicate a power function with an exponent of approximately $\frac{2}{3}$, but a logarithmic function with an inelegant linear disturbance near the bottom cannot be excluded. Both functions cover the range of numbers used in magnitude estimation well, and both show too little compression for the very large numbers.

Similar as they are in terms of fitting the random-production scales for number, these 2 functions have quite different implications for the form of the psychophysical functions of the dimensions to which numbers may be matched. If the scale for number is logarithmic and power functions are obtained in magnitude estimation, then it is unlikely that the function for the estimated dimensions is anything but logarithmic. Ekman (1964) has shown

how power functions will result for magnitude estimation if all continua, including number, have logarithmic psychophysical functions. With a logarithmic function for number, the psychophysical law for the estimated continua cannot be a power function, and whatever psychophysical law they do obey must be virtually indistinguishable from Fechner's (1860).

If, on the other hand, the subjective size of numbers grows as the $\frac{2}{3}$ power of their absolute magnitude, then the power functions found in magnitude estimation imply that the perceived magnitudes of the continua being judged also rise as a power function of the physical measure. The magnitude-estimation function will, however, have an exponent 1.5 times too large. This can be seen from the following considerations. The preceived size of numbers, by this argument, obeys the following function:

$$\Psi_n = k_n N^{\frac{2}{3}},$$

where Ψ_n is the perceived size of numbers, N is the absolute size of the numbers, k_n is an arbitrary constant, and $\frac{2}{3}$ is the exponent in the power function for apparent size of number. If the perceived size of magnitudes on any other dimension, ϕ_1, grows according to the function

$$\Psi_1 = k_1 \phi_1^{\beta},$$

where β is the exponent in the power function for the apparent size of ϕ_1, then the match between numbers and ϕ_1 will give the function

$$N = k_2 \phi_1^{\beta/\frac{2}{3}} = k_2 \phi_1^{1.5\beta}.$$

Even if all exponents from magnitude estimation misrepresent the subjective psychophysical exponent by a common factor, cross-modality matches will still be correctly predicted. Suppose, for illustration of this fact, that S's task is to match 2 continua, ϕ_1 and ϕ_2, and that magnitude estimation gives the following psychophysical power functions:

$$\Psi_1 = k_1 \phi_1^{\alpha}$$

and

$$\Psi_2 = k_2 \phi_2^{\beta}.$$

The predicted match for these 2 continua, when ϕ_1 is adjusted by S to equal the apparent size of magnitudes of ϕ_2, will be

$$\phi_1 = k_3 \phi_2^{\beta/\alpha}$$

(Stevens, 1959).

If the overestimation of the exponents due to the nonlinear scale of number used in magnitude estimation is taken into account, the exponents used for prediction should be $\frac{2}{3}(\alpha)$ and $\frac{2}{3}(\beta)$, and the predicted match should therefore be

$$\phi_1 = k_3 \phi_2^{\frac{2}{3}(\beta)/\frac{2}{3}(\alpha)} = k_3 \phi_2^{\beta/\alpha},$$

which is the same prediction obtained from the magnitude-estimation exponents.

It should be noted that few experiments employing magnitude estimation depend on the precise size of the exponent. Rather, they usually set out to prove that a power function does (or does not) fit a given estimation scale, or else they study relative values of power function exponents. Thus, the conclusions of very few of these experiments would have to be changed if the psychophysical function for number is a power function.

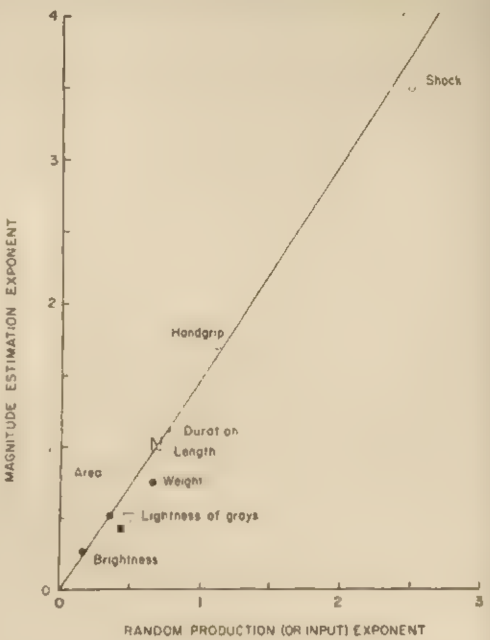

FIGURE 17. Relationship between random-production exponent (open circles) or input (sensory) exponent (filled circles) and that obtained by magnitude estimation for a number of continua. (Linear coordinates.)

Predicting Magnitude Estimation Exponents

If magnitude-estimation scales overestimate the psychophysical exponent by a factor of $\frac{3}{2}$ and if random production yields a scale for the continuum that is unaffected by the numerical response scale, then the magnitude-estimation exponent should equal 1.5 times

the random-production exponent. The degree to which this prediction holds can be seen in Figure 17. In this figure, the open circles show magnitude-estimation exponents for the continua scaled here, plotted as a function of their random-production exponents. Random-production exponents for handgrip, shock, and area were obtained from Banks (1973), and exponents for duration (.75) and length (.68) were estimated from the random-production scales of Experiments VIII and IX. The magnitude-estimation exponents are those reported in Stevens (1961a) except for area, which is an average of the values obtained by Stevens and Guirao (1964), Teghtsoonian (1965), and Curtis and Rule (1972). If the magnitude-estimation exponent is 1.5 times larger than the random-production exponent, these points should fall on a line with a slope of 1.5. As is seen, the points are well approximated by this line.

Also plotted in this figure are points showing the relationship between "input" exponents of the 2-stage model of magnitude estimation (cf. Curtis et al., 1968). These points have been taken from a number of papers on the 2-stage model (Curtis, 1970; Curtis et al., 1968; Curtis & Fox, 1969; Rule & Curtis, 1973) and they summarize results for several continua. Since the input exponent in this model is an estimate of the sensory scale of the continuum without the effect of the numerical response scale, the relationship between the input and the magnitude-estimation exponents should approximate a straight line with a slope of 1.5 and, as seen in Figure 17, it does quite well.

Finally, the N in the figure relates the subjective exponent for number, as estimated in this paper and by Rule and Curtis (1973), to the exponent found in magnitude estimations of number by Rosner (1965), Stevens (cited in Marks, 1968), and Banks (unpublished experiment, 1968). Of course, numerical magnitude estimations of numbers lead to an almost perfectly linear scale, and the N plotted in this figure serves only to determine the slope of the line on which the other points should fall.

Indirect Evidence for a Nonlinear Numerical Response Scale

Given that the psychophysical law for number is a power function with an exponent of about $\frac{2}{3}$, it still remains to be shown that this law governs the use of numbers as responses in a magnitude-estimation experiment. The main reason for studying the subjective scale of number is to determine its effect on magnitude-estimation scales. The psychophysical scales of number generated here may, however, apply only to unconstrained numbers.

The work of Curtis and his colleagues (Curtis, 1970; Curtis et al., 1968; Curtis & Fox, 1969) with the 2-stage model provides the best direct evidence that a decelerated power function of number is at work when estimates of sensory magnitude are made, but there exist some other less direct indications that this is the case. Equisection and related scaling tasks that do not give specific numerical instructions to *S* presumably operate entirely on the subjective continuum. There is no need to assume that *S*s interpret numerical instructions correctly, only that they understand the meaning of equality of sense distances (Torgerson, 1958). If the numerical response scale causes the psychophysical power function derived from magnitude estimation to have too large an exponent, then the scales from equisection and related techniques should be power functions with exponents smaller than those of magnitude estimation. This is usually the case (Stevens, 1961b, 1971a), but the fact that these techniques are subject to bias effects that can lead to internal inconsistencies and to various different predicted psychophysical functions (Garner, 1954b, 1958; Stevens, 1957) makes a more precise comparison with magnitude-estimation scales impossible.

In category scaling, *S* is instructed to space the categories evenly over the stimulus continuum. Although the instructions usually designate the categories with numbers, the task requires only that *S* break the continuum into a number of apparently equal intervals. Here, too, there are a number of sources of bias operating, and the form of the category scale is not solely determined by the individual stimulus magnitudes. Marks (1968) has shown that power functions can describe category scales obtained for a wide variety of continua if it is assumed that the average category ratings are on an interval scale and must be readjusted for unit and zero point. The parameters in the power functions Marks fits to category scales reflect the sources of bias of various experimental procedures, but the exponents always remain below those found in magnitude estimation.

Fractionation and ratio-production scales should, when power functions describe them, have exponents approximately the same as the

magnitude-estimation function for the continuum. This is so because the experimentally prescribed ratios will be interpreted nonlinearly by S, as are numbers in magnitude estimation. These techniques give the same exponent as magnitude estimation when production and fractionation are used together (Scharf & Stevens, 1961; Stevens, 1962), but, individually, the techniques give scales that seem overly subject to procedural biases (Garner, 1954b). It is of interest that Garner (1954a) was able to equate fractionation and equisection scales of loudness by assuming that Ss fractionated according to a ratio of 1:1.7 instead of the prescribed ratio of 1:2. If the power function for perceived number is $\frac{3}{4}$, 1:2 will define a subjective ratio close to 1:1.7. As a further bit of evidence, Stevens (1970, 1971b) has noted that when power functions are fit to neuroelectric correlates of stimulus intensity, the exponent is typically smaller than that for magnitude estimation of the same intensity continuum.

Finally, it should be noted that Stevens (1971a) uses the term "virtual exponent" to refer to the undersized exponents generally produced by the scaling techniques discussed above, and he provides a more thorough review of this topic. Stevens does not, however, give an explanation of why the virtual exponent should be smaller than the "actual" exponent obtained in magnitude estimation. An important advantage of the conclusion that numbers are used nonlinearly in magnitude estimation is that it predicts the general relationship between the virtual exponent and the exponent obtained in magnitude estimation.

CONTENTS—(*Continued*)

Beginning in 1975 the *Journal of Experimental Psychology* will appear as four independently edited and distributed sections:

The **Journal of Experimental Psychology: Human Learning and Memory** (Lyle E. Bourne, Jr., Editor) will publish experimental studies on fundamental acquisition, retention, and transfer processes in human behavior.

The **Journal of Experimental Psychology: Human Perception and Performance** (Michael I. Posner, Editor) will publish experimental studies designed to foster understanding of information-processing operations and their relation to experience and performance.

The **Journal of Experimental Psychology: Animal Behavior Processes** (Allan R. Wagner, Editor) will publish experimental studies concerning the basic mechanisms of perception, learning, motivation, and performance, especially as revealed in the behavior of infrahuman animals. The studies should make significant contributions to general behavior theory.

The **Journal of Experimental Psychology: General** (Gregory A. Kimble, Editor) will publish experimental articles in any of the three areas represented by the above sections when the articles involve a longer, more integrative report leading to an advance in knowledge that is judged to be of interest to the entire community of experimental psychologists. The section will include but not be limited to articles such as those that have appeared as *Journal of Experimental Psychology* monographs and as chapters in contemporary books of "advances." Republication of a limited number of data may be permitted if necessary to make the article complete and definitive.

In some instances it may be difficult for the author to decide whether one of the above listed sections or the *Journal of Comparative and Physiological Psychology* is most appropriate for a given manuscript. The author should weigh the essential implications of the research rather than the specific techniques or subject population employed. Is the central message concerned with the issues and concepts of behavior theory (*JExP*) or with the biological substrates of behavior (*Journal of Comparative and Physiological Psychology*)? Is the study primarily addressed to theory of human behavior (*JExP: Human Learning and Memory* or *JExP: Human Perception and Performance*) or to theories equally or more relevant to infrahuman subjects (*JExP: Animal Behavior Processes*)? Is the major emphasis on the acquisition, retention, or transfer of new information, concepts, or problem-solving strategy (*JExP: Human Learning and Memory*) or on the organization or control of structures or mental operations, where the acquisition of new skills is only incidental (*JExP: Human Perception and Performance*)?

Manuscripts should be sent directly to the Editor of the relevant section at the address listed below. In cases where an Editor believes a manuscript is clearly more appropriate for an alternative journal of the American Psychological Association, he may redirect the manuscript with the approval of the author. A final action taken by one of the Editors will be final for all sections of *JExP*.

Manuscripts should be submitted in triplicate and according to the instructions contained in the *Publication Manual* of the American Psychological Association.

Authors should note that limitations on total pages make it necessary to restrict publication to those papers that in the opinion of the Editors make a notable contribution to the literature. Preference can be expected for sets of interrelated experiments that are definitive or provocative.

Addresses for the 1975 Editors-Elect are as follows: *JExP: Human Learning and Memory*, Lyle E. Bourne, Jr., Department of Psychology, University of Colorado, Boulder, Colorado 80302; *JExP: Human Perception and Performance*, Michael I. Posner, before June 1, 1974, same as Allan R. Wagner, after June 1, Department of Psychology, University of Oregon, Eugene, Oregon 97403; *JExP: Animal Behavior Processes*, Allan R. Wagner, Department of Psychology, Yale University, 333 Cedar Street, New Haven, Connecticut 06510; *JExP: General*, Gregory A. Kimble, Department of Psychology, University of Colorado, Boulder, Colorado 80302.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1974: $60 domestic, $61 foreign, $6 single issue. APA member rate: $25. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive galley proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., 175 Fifth Avenue, New York, New York 10010; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. Undelivered copies resulting from address changes will not be replaced; second-class mail is not forwarded unless subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published monthly in two volumes, six issues per volume, by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W., Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and additional mailing offices.

RHYTHMIC STRUCTURE IN AUDITORY TEMPORAL PATTERN PERCEPTION AND IMMEDIATE MEMORY[1]

PERSIS T. STURGES
California State University, Chico

JAMES G. MARTIN[2]
University of Maryland

In 3 experiments, *S*s heard continuous sequences of 14 or 16 binary elements (high- and low-buzz tones). These were either 7-element or 8-element patterns repeated once. Dummy sequences were included also to provide a *same–different* (repeating or changed) judgment task. The *S* also wrote each sequence. Half of the patterns of each length followed a rule for rhythmic structure and half did not. Of particular interest is that 7-element patterns, though shorter than 8-element patterns, cannot have a simple rhythm. In general the results were that rhythmic patterns were more easily recognized as repeating than nonrhythmic patterns, and 8-element patterns were more easily recognized as repeating than 7-element patterns. Similar results held for written recall.

Martin (1972) has presented a view of real-time information processing in which the perception and production mechanisms underlying temporally unfolding behavior are linked by the concept of rhythmic action. Very briefly, the basic notions are these. Natural constraints on human movement entail that sequences of movement-produced sounds, e.g., connected speech and music, are rhythmically patterned, i.e., they are sequences of "accented" and "unaccented" elements temporally organized *in a certain way.* A descriptive rule has been proposed for characterizing the organization of these natural patterns and shows that their temporal structure is based upon relative timing constraints which go beyond the simple ordering (concatenation) of elements. The rule also shows the way in which rhythmic patterns have a hierarchical structure.

Of relevance here is the relation between characteristics of a stimulus, in this case auditory temporal patterns, and the way the stimulus is processed (Garner, 1970b). If auditory stimulus sequences normally occurring in the natural environment are characteristically organized in a certain way, e.g., they are rhythmic, then one might reasonably expect that perceptual mechanisms as they have evolved will be biased to listen for sounds organized in this certain way. This basic notion underlies the present work.

If an auditory pattern is rhythmic, one of its properties is that certain elements in the pattern, main accents in particular, are temporally redundant. The potential

[1] This research was supported by U.S. Public Health Service Grant MH-16726 from the National Institute of Mental Health to the second author, and by a grant from the Biomedical Sciences Support Committee, University of Maryland, to the Center for Language and Cognition. Nancy Hurlbut, Dianne Reamy, Judith Sprei, and Judith Zachai helped with the experiments. Experiment III was reported at the meeting of the Psychonomic Society, St. Louis, November 1971.

[2] Requests for reprints should be sent to James G. Martin, Department of Psychology, University of Maryland, College Park, Maryland 20742.

consequence for perception of such an organization of the input sequence is that once early accents in the pattern are heard, later accents, and the end of the pattern as well, can be anticipated in real time. The question of interest then is whether perceptual mechanisms are in some way designed to make active use of these temporal redundancies in the pattern during the on-line input of the pattern itself. Alternatively, one could postulate a mechanism that treats the sequence of elements in a pattern as a concatenated string, so that even if there are temporal redundancies in the sequence these redundancies are ignored during listening and the elements registered one by one as they are heard, in left-to-right fashion. A further alternative, if elements occur at rates too fast to be handled sequentially, as in speech (Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967), is to suppose that processing of the sequence consists in first accepting a whole string of elements, e.g., those making up a phrase or other "decision unit" (Miller, 1962), and then processing the whole string simultaneously upon reaching the end of the unit, the occurrence of which has just been signaled by a pause or other terminal cue. This alternative also does not take account of any temporal redundancies in the sequence, and, like the analysis-by-synthesis (Halle & Stevens, 1964) and similar models, would appear to require extremely rapid processing between decision units. By contrast, the present theory suggests that the mechanisms for on-line listening in real time are optimally designed to make use of the temporal redundancies always present in humanly produced, i.e., rhythmically structured, sound inputs. The redundancies are highly correlated with the distribution of information (melodic or linguistic) in the sequences and hence are not ignored but are made use of during ongoing perception in a highly efficient way (Martin, 1972).

Since human sound patterns are inherently rhythmic, however, these notions cannot easily be tested using intact spoken or other humanly produced sounds. One possibility is to temporally distort connected speech sequences in some artificial way. Another is to use electromechanically timed nonspeech sounds, as w[illegible] in the present experiments. *Same–d*[illegible] judgments were used in the experimen[illegible] to get at the more perceptual aspects of input processing. However, inputs in memory experiments also are frequently sequential so that, in the present view, the results of memory experiments also can be affected by the temporal structure of the input. A conventional memory task—written recall—was used to show that this is the case.

The stimulus inputs used in the experiments were repeating auditory temporal patterns consisting of sequences of evenly spaced high- and low-buzz tones. Each pattern was either 7 or 8 elements in length, and began with a high tone and ended with a low tone. The first (high) tone was assumed to be heard as accented, as were all following run-initial high tones. Some patterns were rhythmic as defined by the rhythm rule presented elsewhere (Martin, 1972), and some were [illegible]t. For instance, a sequence of 8 equidistant elements is rhythmic for present purposes if accents are located on elements in Serial Positions 1 + 3 and/or 5, i.e., accents are 2 elements apart or some very simple multiple thereof. In consequence, hearing the early accents in a pattern generates expectancies concerning later accents. Additionally and just as important, these patterns generate expectancies concerning their termination (an even-numbered element), hence expectancies concerning when they begin repeating (an odd-numbered element). By contrast, an 8-element pattern is nonrhythmic if accents are located on Elements 1 + 4, since this pattern of accents generates initial expectancies for triplets.[3] Such expectancies will be violated, since triplets are appropriate for 9- (or 6-) element patterns but not for 8-element patterns. Further examples of nonrhythmic patterns are those having

[3] Obviously there cannot be accents on Positions 3 or 5 if there is one on Position 4, if accents are defined as run-initial high tones.

accents on Elements 1, 4, and 6, or on 1, 3, and 6. These patterns mix duples and triplets, hence generate either conflicting expectancies or else no expectancies in particular, including expectancies concerning the termination of the pattern. Thus, receiving no impression of a coherent pattern during listening, it should be more difficult for *S* to recognize the pattern as repeating or to recall it.

Besides rhythmic and nonrhythmic 8-element patterns, matching 7-element patterns were also used in the experiments. These are interesting because while they are shorter than 8-element patterns, hence on most theories should require less processing, they cannot have a simple rhythm, i.e., accents cannot be equidistant.[4] To demonstrate to yourself that 8-element patterns are simpler and more natural than 7-element patterns, tap an 8-element pattern on your desk, continuously and repeatedly, as fast as you can, accenting Taps 1, 3, and 5. Then try a 7-element pattern, again accenting Taps 1, 3, and 5. If not immediately convinced, practice a bit. For most people it may take some time before the 7-element patterns become smoothly and evenly repeated. On the present view, the relative naturalness of evenly spaced accents during production has consequences for perception also, which can be demonstrated under appropriate experimental conditions. For instance, a repeating 7-element pattern with accents on Elements 1 and 5, or on Elements 1, 3, and 5, generates expectancies during listening for an 8-element pattern which, however, will be violated since the expected pattern begins repeating one element too soon. In consequence, it should be harder to recognize the pattern as repeating. Additionally, with respect to memory, 7-element patterns should also be harder to recall than 8-element patterns, even if, as in these experiments, 7- and 8-element patterns are equivalent in number and location of accents, and in number of runs, "groups," "chunks," etc., dif-

[4] Of course, there are 7-beat musical rhythms, but these require more sophisticated responses in perception or production than do simpler rhythms.

10001110	1000110	10011100	1001100
11001000	1100100	11010000	1101000
11101000	1110100	11100100	1110010
11001110	1100110	11000110	1100010
10101000	1010100	10110110	1011010
10101110	1010110	11010100	1101010

Note. 1 = high tone and 0 = low tone. Good refers to rhythmic patterns and poor refers to nonrhythmic patterns.

fering only in that one group (or chunk) is smaller.

Experimental patterns were presented continuously, but only twice, i.e., repeated only once. The 7- and 8-element patterns were mixed. There were also dummy patterns that changed somewhat, i.e., did not repeat exactly, so that *S*'s first task was to judge *same–different*, i.e., repeated or changed. The second task was to write the pattern(s). The 3 experiments were identical except for presentation rate and response delay time, and will be discussed together whenever convenient.

Method

Experiment 1

Subjects and design. The *S*s were 44 undergraduates from the University of Maryland. Rhythmic structure (rhythmic vs. nonrhythmic) and pattern length (7 vs. 8 tones) were combined factorially as within-*S*s variables.

Materials. The buzz tones were approximately 180 Hz. (high) and 150 Hz. (low) presented at a 3.3/sec rate. The tones were 200 msec. long, with 100-msec. silent intervals between them.

The experimental, or repeating (*same*), patterns are shown in Table 1. Each begin with a high tone as preferred by most *S*s (Royer & Garner, 1970) and assumed to be heard as accented (Garner, 1970a). Looking at 8-element patterns first, the "good" (rhythmic) patterns had accents (single or run-initial high tones) on Serial Positions 1 and 5, and in 2 cases also on Position 3. The "poor" (nonrhythmic) patterns had accents on Positions 1, 4, and/or 6.

As Table 1 shows, each 8-element pattern was matched by a 7-element pattern constructed by deleting one item from the end of a run in its matching 8-element pattern at Serial Position 6 or 7. Thus, the 7- and 8-element patterns were exactly equivalent in the number of runs and in the number and location of accents. They were

TABLE 2

MEAN PROPORTION CORRECT JUDGMENTS

Experiment	Pattern			
	8-element-good	8-element-poor	7-element-good	7-element-poor
I (N = 44)	.80	.74	.77	.71
II (N = 24)	.80	.74	.73	.61
III (N = 42)	.80	.58	.69	.53

Note. Good refers to rhythmic patterns and poor refers to nonrhythmic patterns.

also equivalent in number and content of groups, chunks, etc., except that one group (or chunk) in the 7-element pattern was smaller (shorter). Each pattern was recorded twice continuously (repeated). Thus, each sequence was presented as a series of 14 equal-interval tones (the 7-element patterns) or 16 equal-interval tones (the 8-element patterns).

In addition to the 6 repeating (*same*) patterns of each type in the 2 × 2 design there were also 4 dummy patterns of each type that did not repeat but were changed slightly (*different*). These dummy sequences are not shown. For each of the dummy subsets, as in the experimental subsets (Table 1) there were 2 3-accent patterns and 4 2-accent patterns; in each of the subsets, half of the elements were high tones and half were low tones.

The 40 patterns (24 experimental and 16 dummy) were combined in a mixed list and were divided into 2 blocks of 20 patterns each with the following restrictions. Half of each subset of items was in each block and only one of each pair of matching 7- and 8-item patterns was in each block. In order to avoid repetition effects, whenever (half of) a dummy sequence was the same as an experimental pattern it always followed the experimental pattern in the block. Half of the *Ss* heard Block A first; the other half heard Block B first.

Procedure. The *Ss* first heard practice sequences with instructions to write the pattern. A nonrepeated pattern of each length was presented first, then 4 repeating patterns, one each of a 7- and 8-element pattern repeated (*same*) and changed (*different*). After hearing each sequence, *Ss* made their judgments, wrote the entire pattern, and were given feedback about the correct responses. No feedback was given during the presentation of the experimental patterns that followed

The *Ss* in small groups heard the sequences monaurally through headphones and responded after each on an answer sheet which for each sequence provided the letters *S* and *D* and 2 solid lines for writing the 2 patterns. The *Ss'* first task was to judge *same* or *different* and circle *S* or *D*. The *Ss'* second task was to write the entire sequence whether repeating or changed with 1 representing a high tone and 0 a low tone. They were told that each pattern began with a high tone and ended with a low tone, to guess if uncertain, and to mark an X when unable to guess.

Experiment II

The *Ss* were 24 undergraduates fr[illegible] versity of Maryland. This experiment [illegible] to Experiment I except that the tones [illegible] sented at the rate of 4.4/sec. The ton[illegible] 150 msec. long, with 75-msec. silent inte[illegible] between them.

Experiment III

The *Ss* were 42 undergraduates from the University of Maryland. This experiment was identical to Experiment II except that after each presentation of the sequence there was a 4-sec. unfilled forced-delay interval before *Ss* could respond. The answer sheet had 3 lines, labeled A, B, and C, for each sequence. Four seconds after the end of the sequence *E* held up a card showing either A, B, or C to indicate the line on which *S* was to write his responses.

RESULTS

The following results are for the experimental sequences only; data for dummy sequences are not reported.

Judgments

The mean proportions of correct judgments over the 2 trials are shown in Table 2. For all experiments there were more correct judgments for good patterns than for poor patterns, as predicted: Experiment I, F (1, 43) = 7.90, $p < .01$; Experiment II, F (1, 23) = 11.01, $p < .01$; and Experiment III, F (1, 41) = 56.38, $p < .001$. For Experiment I the judgments for the 8-element patterns were no[illegible] significantly better than for the 7-[illegible] patterns, F (1, 43) = 2.94, $p < .10$. For Experiments II and III this difference was significant: Experiment II, F (1, 23) = 11.20, $p < .01$, and Experiment III, F (1, 41) = 9.55, $p < .01$. There were no interactions. In short, good patterns were more easily recognized as repeating than were poor patterns in all 3 experiments. Except for Experiment I (slower presentation rate), 8-element patterns were more easily recognized as repeating than 7-element patterns, as predicted.

Pattern Recall

Two measures were analyzed. The first was the number of repeating patterns

TABLE 3

Mean Correct Pattern Recall

Experiment	Trials 1 and 2 combined				Trial 2 plus judgment correct			
	8-element-good	8-element-poor	7-element-good	7-element-poor	8-element-good	8-element-poor	7-element-good	7-element-poor
I	4.25	2.15	3.78	2.88	2.30	1.14	2.02	1.59
II	2.92	1.63	2.25	1.67	1.75	.96	1.00	.75
III	3.00	1.14	2.73	1.12	1.79	.69	1.43	.48

Note. Good refers to rhythmic pattern and poor refers to nonrhythmic pattern.

completely correct over the 2 trials combined, ignoring the second half of the written response and also whether or not the *same–different* judgment was correct. The Trials 1 and 2 combined data in Table 3 show that in all 3 experiments there was better pattern recall for the good than for the poor patterns: Experiment I, F (1, 43) = 29.27, $p < .001$; Experiment II, F (1, 23) = 11.51, $p < .01$; and Experiment III, F (1, 41) = 58.70, $p < .001$. Using this response measure, there was no significant overall difference between 8- and 7-element patterns on any of the experiments (although the direction was in favor of 8-element patterns in the last 2 experiments). In Experiments I and II there was a significant interaction: Experiment I, F (1, 43) = 8.71, $p < .01$, and Experiment II, F (1, 23) = 6.16, $p < .025$. These interactions mean that the longer patterns gain relatively more when the patterns have a good structure, namely, rhythmic.

The second written recall measure was the number of patterns completely correct on Trial 2 when S also had accurately judged the pattern as repeated. They have the advantage of practice and of more confident judgments and should be somewhat more reliable. The Trial 2 plus judgment correct data in Table 3 show that for all 3 experiments the good patterns were easier than the poor patterns: Experiment I, F (1, 43) = 16.59, $p < .001$; Experiment II, F (1, 23) = 6.51, $p < .05$; and Experiment III, F (1, 41) = 52.36, $p < .001$. In Experiment I there was an interaction, F (1, 43) = 7.76, $p < .01$, again showing the relative disadvantage of greater length when the patterns were nonrhythmic. For Experiments II and III the 8-element patterns were recalled significantly better than the 7-element patterns: Experiment II, F (1, 23) = 8.46, $p < .01$, and Experiment III, F (1, 41) = 7.43, $p < .01$.

In short, rhythmic patterns are generally easier to recall than nonrhythmic patterns. Extra length depresses recall for nonrhythmic (nonstructured) sequences but not for rhythmic sequences.

Discussion

Under the conditions of these experiments, auditory temporal patterns generally were more difficult to recognize as repeating when they were nonrhythmic than when they were rhythmic, and were often less easily recalled when nonrhythmic than when rhythmic. This result generally held even when the rhythmic patterns (8-element good) were made nonrhythmic, or at least rhythmically more complex, by simply reducing their length (7-element good). Considering the recognition (judgment) task first, these results appear to go against element-by-element registration as a useful perceptual strategy, either deliberate or "automatic," particularly when the input rate is fairly rapid (Experiments II and III). (This is not to say that the listener could never profit by attempting such a strategy.) It is also unlikely that the listener in any sense compares the 2 patterns in the sequence by somehow holding them as units in echoic memory. Also unlikely is that the differences between 7- and 8-element patterns could be explained by some measure of sequential complexity other than rhythmic complexity, since only on rhythmic grounds is it easy to see why taking one element out of a run (or subgroup) should make the pattern more complex. More likely is that the listener "feels" the coherence of a rhythmic pattern

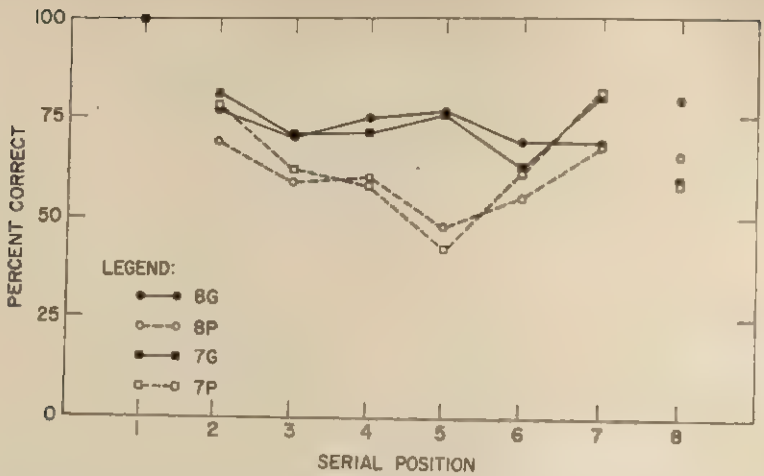

FIGURE 1. Serial position curves for the second trial of Experiment III. (The first 8 positions are shown, so that for 7-element patterns the last position represents the first element of the pattern as it was repeated. Abbreviations: G = good, i.e., rhythmic pattern, and P = poor, i.e., nonrhythmic pattern.)

as he hears it, and since this includes the "knowledge" that the pattern has terminated, hence the beginning of the next, the remainder of the sequence is more readily recognized as a repetition of the pattern just heard. This conclusion, that rhythmic patterns are somehow "easier" or more "natural," supports the hypothesis that listening mechanisms are optimally designed to handle sequential inputs that have a rhythmic organization.

It should be mentioned that an alternative experimental method would have been to present patterns of a given length in blocks, so that *S* would know in advance which length to expect, and hence could use various deliberate strategies. There is little doubt that *S* would do better with 7-element patterns than 8-element patterns under such conditions (though not better with poor patterns than with good patterns). This conclusion is hinted at in Table 1, which shows insignificant main effects of pattern length on judgments with the slower rate in Experiment I. But results favoring shorter patterns are not interesting in themselves since they are expected on nearly any theory of information processing.

Turning to written recall, consider the serial position curves in Figure 1, which were obtained from the second trial of Experiment III (similar curves were obtained from Experiments I and II). Position 8 was scored as correct for the 7-element patterns only when left blank. For 8-element patterns it was scored correct if 0 was recorded but incorrect either for 1 or a blank.

These curves are not quite conven[illegible]nal in several respects. For one, they repres[illegible] the first half of the sequences actually presented to *S* and his responses. For another the point representing the first tone is [illegible] connected to the following points, since [illegible] knew it was always high, and Position 8 in the sequence is not connected. The *S* would know whether this was high or low if he knew the length of the pattern he had just heard. Obviously he often did not, as can be seen by noting the poor scores at Positions 7 and 8.

Several aspects of these curves are of interest. For one, when Positions 1 and 8 are disregarded, the curves for good patterns are relatively flat. Poor patterns, on the other hand, show the dip in the middle typical of serial position curves for arbitrary sequ[illegible] of memory items. This result, however, may be in part a response bias toward writing good patterns, e.g., toward marking Position 5 as accented. Such a bias would result in an elevation at that position for good patterns and a depression for poor patterns, both tendencies of which can be seen in Figure 1.[5] Further suggestions for a response bias can

[5] This point was tested by linear contrasts of Position 5 against the average of Positions 4 and 6 for each of the 4 string types. All but the 8-element-good patterns were reliable ($p < .01$).

be seen in Table 3. Here, although the input stimuli were the same in Experiments II and III, the delay in Experiment III resulted in lower scores for 8- and 7-element-poor patterns, compared to Experiment II, but higher scores for 7-element-good patterns (8-element-good patterns remained unchanged). These results suggest a "drift" toward good patterns during the delay interval. Both of these tendencies, a flat serial position curve and a response bias in favor of good patterns, are to be expected on the view that rhythmic patterns are gestaltlike holistic entities.

Another result seen in Table 2 is worth mentioning. While the input sequences were exactly the same in Experiments II and III, the latter required *S* to make a delayed response. Comparing Experiments II and III, note that the delay depressed correct judgments for nonrhythmic patterns. Why should this happen, since presumably the judgments are made immediately even if the written response must wait? Most likely, the answer is that when patterns are nonrhythmic the impression of a coherent pattern is less firm and evaporates quickly over time, with the result that *S* now reports that the pattern did not repeat.

Finally, speculating on the implications of these experiments, the main point concerns the hypothesis that meaningful auditory patterns occurring in nature generally have a temporally redundant (rhythmic) organization, and that perceptual mechanisms have evolved to expect and make use of these redundancies. The importance of temporal structure can be seen in the fact that simple musical tunes remain recognizable when pitch variations are eliminated with timing relationships intact, but not vice versa (Lenneberg, 1967). A sequence (concatenation) of notes is not a tune unless the notes are in the right temporal places. Similarly, speech appears to be organized in such a way that the more informative linguistic elements are temporally predictable, i.e., organized around the accent structure of the sequence (Martin, 1972). It is natural to speculate that the temporal redundancies in speech at the level of sound facilitate relatively "automatic" processing at that level, thus freeing psychological resources for "attending" to the level of meaning. The fact that spontaneous speech departs from the received grammar, yet is understood nevertheless (Martin, 1967), is in line with this view. The listener can depend upon temporal, if not syntactic, regularities in the speech he hears.

MEASURES OF INFORMATION PROCESSING IN CONCEPT IDENTIFICATION [1]

DALE E. BERGER [2]

Claremont Graduate School

A method was developed to show multiple-hypothesis behavior and states of information during concept identification (CI). Compared to Levine's 1966 blank-trial method, the new method provided more detail about information held by *S* at each stage of a problem and allowed examination of process assumptions of current CI models. Most *Ss* attempted to process information on all dimensions simultaneously; some initially selected a subset of dimensions to process. Processing errors were made following positive as well as negative feedback. No CI model could account for the data in detail, although protocols from individual *Ss* were consistent with aspects of the various models. A random-reversal assumption was suggested as a mechanism to account for departures from perfect processing.

Recent theoretical approaches have discussed behavior in concept identification (CI) tasks within the framework of hypothesis testing. Much of the work (e.g., Bower & Trabasso, 1964; Falmagne, 1972; Levine, 1966; Trabasso & Bower, 1968; Wickens & Millward, 1971) grew out of the "strategy selection" theory formulated by Restle (1962). This theory postulates sampling with replacement from a known set of hypotheses following each error.

Since the original investigation by Bruner, Goodnow, and Austin (1956), researchers have been concerned with the difficulties of externalizing strategies used in attaining concepts. This remains a most difficult problem. In a recent review of research on strategies in CI, Taplin and Jeeves (1972) concluded that valid and reliable indices of the processes of CI must be established if information-processing theories are to remain a promising approach to understanding concept attainment.

Levine (1966) introduced a technique that provides some information about hypothesis behavior of individual *Ss* i CI task. Assuming *S*'s responses betwe errors are determined by a single hypothesis, the pattern of responses to a set of blank trials (trials with no feedback) can be used to identify the hypothesis. Levine's blank-trial technique has been used extensively in testing implications of mathematical models of CI (cf. Erickson, 1968; Levine, 1969).

Levine's (1966) hypothesis-tracking technique will be called multiple-cue (MC) to contrast it with an alternative single-cue (SC) technique introduced in experiments to be reported here. The difference is in the complexity of the stimuli used for blank trials: The MC method uses complex stimuli which each have a value on every dimension, whereas the SC method uses stimuli which each have only one value on a single dimension (see Figure 1).

With the SC blank-trial technique, each stimulus dimension is represented in the blank-trial set by a single value presented in isolation. The *S* is given 3 response alternatives to SC stimuli: If he feels the cue is potentially relevant to solution, he is allowed to classify it into the correct category; if he has eliminated the dimension from the set of possible solutions, he would respond *irrelevant*; if he does not remember how the cue should be classified, he would respond *don't remember*. When a set of SC blank trials follows every feedback

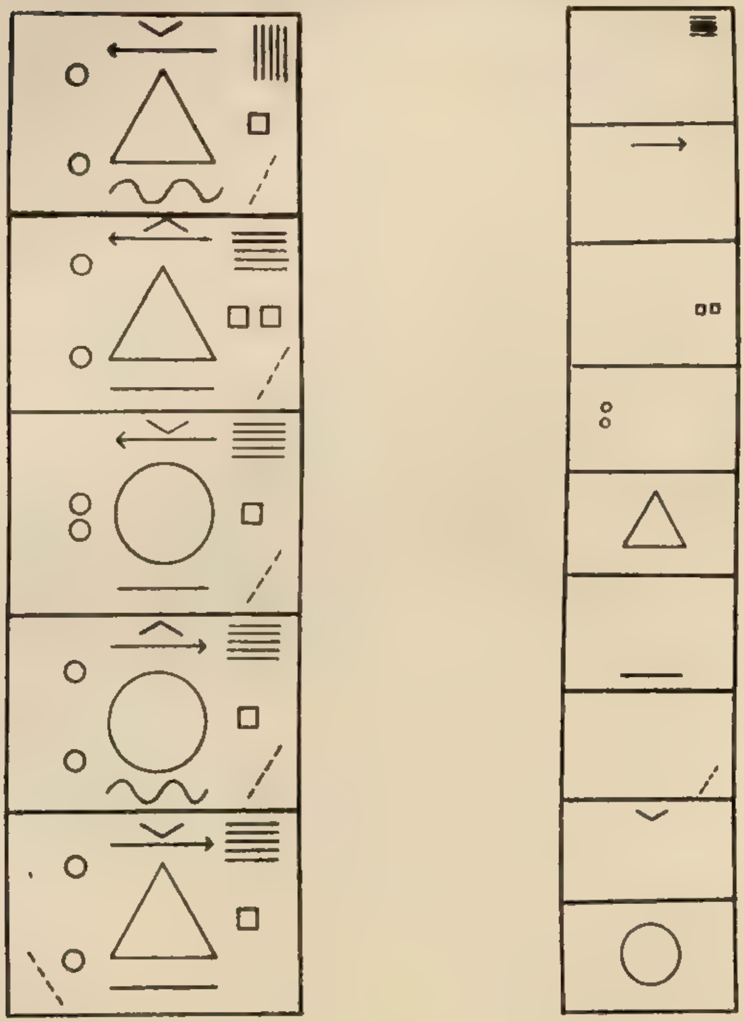

FIGURE 1. Examples of multiple-cue and single-cue blank-trial test sets.

trial (FT), it is possible to recover the information *S* has on each dimension at each stage of the problem.

The SC blank-trial procedure allows detailed examination of processing errors during the course of solving a CI problem. Eight types of errors account for all possible deviations from perfect processing. Table 1 shows the possible combinations of information held on a given dimension before an FT, the direction of the feedback, classification after the feedback, and the type of processing error, if any. If a dimension is thought to be relevant, it can be classified in either of 2 directions, labeled A and B in Table 1. Note that for the purpose of classifying errors, a *don't remember* response is here considered equivalent to *irrelevant* since both indicate that *S* is unable to classify the dimension.

The 8 types of errors or deviations from perfect processing in a simple binary CI task are as follows:

1. *Initial omission*—a failure to classify

TABLE 1
POSSIBLE ERRORS IN SIMPLE CONCEPT IDENTIFICATION PROBLEMS

Classification before feedback trial	Feedback (consistent with Category A or B)	Classification after feedback trial	Type of error (if any)
No hypothesis (before first feedback trial)	A	A	(Correct)
		B	Initial reversal
		Irrelevant	Initial omission
A	A	A	(Correct)
		B	Inconsistency reversal
		Irrelevant	Premature elimination
	B	A	Failure to eliminate
		B	Consistency reversal
		Irrelevant	(Correct)
Irrelevant	A	A	Consistent resample
		B	Inconsistent resample
		Irrelevant	(Correct)

a dimension in either direction following the first FT (FT_1), because information has either been forgotten or was never encoded.

2. *Initial reversal*—classification, following FT_1, of a value on a dimension opposite to the direction supported by FT_1.

3. *Failure to eliminate*—retaining a hypothesis following an FT where the hypothesis could logically be eliminated.

4. *Premature elimination*—elimination of a dimension before it could logically be eliminated.

5. *Consistency reversal*—reversal of the previous classification on a dimension, making the new classification consistent with the last FT. Since information from the last FT was inconsistent with information held previous to the FT, the dimension should have been eliminated.

6. *Inconsistency reversal*—reversal of the previous classification on a dimension, making the new hypothesis inconsistent with the last FT. Since information on the last FT was consistent with the previous hypothesis, this hypothesis should have been maintained.

7. *Consistent resample*—classification of a dimension which had previously been considered irrelevant to the solution in a way that is consistent with the last FT.

8. *Inconsistent resample*—classification of a dimension that had previously been considered irrelevant in a way that is inconsistent with the last FT.

Distributions of processing errors from individual *S*s can be used to test assumptions of various models of CI. For example, the hypothesis-manipulation model (Chumbley, 1969) assumes perfect processing following a correct response but massive resampling following a proportion $(1 - t)$ of error trials. Thus, resampling errors are the only errors predicted by the model, and they are expected to occur only following an error trial.

It should be noted that the MC blank-trial technique does not provide enough information to allow a comparable detailed examination of the assumptions of models. Only one hypothesis can be revealed by each MC blank-trial set, so it is impossible to determine which other hypotheses *S* may be tracking at that time.

The present experiment was designed to compare the MC and SC blank-trial techniques and to generate distributions of processing errors so models of CI could be evaluated. In a preliminary study with 4-dimensional CI problems, practiced college students performed so well that most made too few processing errors of any type to allow detailed analysis (Berger, 1970). However, performance was poorer on problems with interpolated MC blank trials than on problems with SC blank trials. The present experiment was an extension to more difficult problems with 8 dimensions. Differences between the SC and MC test procedures were reduced by signaling the trials on which *S* would receive feedback, and the effect of the interpolated tests on solution rate was evaluated by comparison with a control condition which had no interpolated tests.

METHOD

Subjects. The *S*s were volunteers from introductory psychology classes at the University of California, Los Angeles, who were fulfilling a class requirement. They were paid $1.50/hr for any time beyond their class requirement. Twenty-four *S*s participated in the experimental group, and 10 *S*s were used in a control condition.

Apparatus and materials. Stimuli were rear projected onto a screen in front of *S* by a Sawyer 550ER projector. A Davis timer was used to control the presentation of feedback. The response panel contained a button labeled "next" to advance the projector, and 4 labeled response choice buttons. There was 1 response button for each of 2 classification categories, a button labeled "irrelevant," and a button labeled "don't remember." The 2 category buttons had lights over them to indicate feedback. Also, there was a small light directly below the screen to signal the FTs.

The FT and MC test patterns each contained 8 binary attributes, and the SC stimuli each consisted of a single value (see Figure 1).

Problems. The stimulus sets used for FTs were arranged so that within each set every pattern differed from every other pattern on exactly half of the dimensions. Thus, an *S* who processed information perfectly would eliminate half of the remaining solutions on each FT. Since there are 16 elementary hypotheses in a problem with 8 binary dimensions, an *S* who eliminated half of the hypothesis following each FT would be left with a single hypothesis following FT_4. Five FTs were given in these experiments, since it was anticipated that most *Ss* would not solve these problems as rapidly as was logically possible. The problems were arranged so that each of the elementary hypotheses was the correct solution equally often.

Patterns in each test set for the MC blank trials met the requirements that (*a*) each stimulus differ from all other stimuli in the set on exactly half of the dimensions, and (*b*) both values of each dimension occur at least once in each test set. These restrictions insure that within each subset it is impossible for *S* to be correct every time if he responds on the basis of a response bias, and if *S* responds on the basis of a single hypothesis, his response protocol for any subset is unique for each of the possible hypotheses. Only 4 patterns are actually necessary in the subset to determine the hypothesis with which *S* responded, but following Levine (1966), a fifth pattern was included to provide a consistency check (see Figure 1).

The set of patterns for the SC test trials consisted of 9 stimuli, each composed of 1 value on a single dimension. The first 8 patterns included 1 value from each of the 8 dimensions, and the ninth pattern served as a consistency check. With equal frequencies, this last pattern was the complement of a value which had occurred earlier in Position 1, 3, 5, or 7 in the test set.

The problems alternated between those with SC and those with MC tests following each FT. The control condition had no interpolated tests, but both types of tests were given after the last FT in all conditions, and *S* was asked what he knew about the problem.

Procedure. Since the focus of the experiment was on asymptotic behavior, extensive training was given to *Ss*. Every *S* attempted 7 practice problems with 4 dimensions and 4 practice and 16 experimental problems with 8-dimensional patterns. The *Ss* in the control condition were given the same instructions and practice problems. Most *Ss* required less than 3½ hr.

TABLE 2

COMPARISON OF BEST AND POOREST *Ss* ON PROPORTION OF PROBLEMS SOLVED AND INCONSISTENCIES ON MULTIPLE-CUE (MC) AND SINGLE-CUE (SC) BLANK-TRIAL SETS

S	Solution rates[a]				Inconsistencies	
	1	2	3	4	MC	SC
Best[b]	.50	.66	.70	.70	.198	.041
Poorest[c]	.08	.06	.19	.23	.242	.173
Control[d]	.20	.38	.43	.45	—	—

[a] Blocks of 4 problems.
[b] $n = 11$
[c] $n = 13$
[d] $n = 10$.

After *S* responded to a pattern, he pressed a central button labeled "next." This stepped the projector and brought *S*'s hand to a neutral position. On FTs, this also caused a light to appear for 1 sec. between the label and button of the correct class. The feedback light appeared just after the stimulus was removed, and was off before the next stimulus was projected.

In response to an MC pattern, *S* had to press 1 of the 2 classification buttons. Given an SC pattern, *S* had 3 options. If he thought the value had always been consistent with only 1 category, he was to press the corresponding button. If the value had been paired with both categories, he was to press the *irrelevant* button. If he could not remember to which category the value belonged, he was to press the *don't remember* button.

RESULTS AND DISCUSSION

Each *S* attempted 16 experimental problems. After the last FT in each problem, every *S* was given an SC and MC test series and was asked what he knew about the problem. An *S* was considered to have solved a problem when the results from both cue tests agreed with the correct hypothesis. Individual differences were very large, with *Ss* solving 0–13 of the 16 problems. The 11 best *Ss* solved at least 7 problems, and none of the remaining 13 *Ss* solved more than 4 problems. Because of this natural break, *Ss* were divided into 2 groups of unequal numbers for subsequent analyses. Overall performance improved rapidly over the first half of the experiment, and was relatively stable during the last half (Table 2). By the

second block of 4 problems, the better *S*s were performing nearly as well as they did during the rest of the experiment. The poorer *S*s, however, did not show much improvement until the third block of problems, and it is likely that they were still improving at the end of the experiment.

Comparison of tests. The 2 types of interpolated tests yielded similar accounts of the composition of the hypothesis sets after FT_5. Of the 384 problems (16 problems from 24 *S*s), both tests agreed that the correct solution had been reached on 142 problems, and on 62 problems, both tests agreed that a particular incorrect hypothesis had been reached as a solution. On 149 other problems, the SC test indicated that *S* was tracking more than 1 hypothesis following FT_5. The remaining 31 problems showed inconsistencies on the MC test, failure to track any hypothesis on the SC test, or disagreement between the 2 tests.

Effect of interpolated tests. In contrast to the pilot studies where SC problems were easier than MC problems, the proportions of SC and MC problems solved were exactly the same, 71/192 = .37. The signal that *S*s in the present experiment received at the beginning of FTs to distinguish them from MC blank trials is probably a relevant factor here. On each trial, the stimulus was removed before feedback was given, so the signal probably helped *S* to avoid processing irrelevant information in the MC blank trials and thus made the 2 probe tests more comparable.

The effect of interpolated test series on overall rate of problem solving can be gauged by comparing the proportion of *S*s who solved each experimental problem with the control condition. Ten *S*s in the control condition solved the same problems as experimental *S*s, but the 5 FTs had no tests interpolated between them. There was no difference in the proportion of problems solved by control *S*s (58/160 = .36) and by experimental *S*s(.37), so the interpolated tests did not influence overall rate of solving.

Inconsistencies in multiple-cue tests. The overall proportion of MC test protocols that were not consistent with any single hypothesis was .222. There was no difference between the best and poorest *S*s, U (11, 13) = 56.5, $p > .25$ (see Table 2).

Inconsistencies in MC test protocols have been interpreted as being the result of random response errors, sometimes called "oops errors" (Levine, 1969). However, an analysis of the inconsistent response protocols showed that they were not all due to random response errors since many could be attributed to a response rule used by *S*s. The "response bias" rule of responding with the same category name to each stimulus in the MC test series was used more often than chance by 19 of the 22 *S*s who showed MC inconsistencies (one-tailed binomial, $p < .001$). Also, the likelihood of an inconsistency on the last MC test depended on the number of hypotheses that *S* was tracking. When the SC test following the last FT indicated that more than 1 hypothesis was considered to be possibly relevant, .161 of the MC test protocols were inconsistent, whereas only .041 were inconsistent when only 1 hypothesis was tracked on the SC test, $\chi^2(1) = 4.48$, $p < .001$.

Inconsistencies in single-cue tests. Nine blank trials were used in each SC test set. Each of the first 8 trials tested a different dimension, and the ninth provided a consistency check by retesting 1 of the 8 dimensions with the value opposite that which had occurred earlier. An inconsistency was said to have occurred if the test and retest did not give the same results. The best *S*s had a much lower proportion of SC inconsistencies over the 5 FTs than did the poorest *S*s, an average of .041 compared with .173 per test, U (11, 13) = 4, $p < .001$ (see Table 2). An SC inconsistency could indicate guessing, a response error, a hypothesis change, forgetting during the course of the set of blank trials, or that *S* had not integrated the information available on the given dimension so that it could be applied equally to both values.

It should be noted that an inconsistency does not necessarily have the same meaning

for an SC and MC test. An SC inconsistency means S failed to classify the 2 complementary values from a dimension in a consistent manner, while an MC inconsistency means S did not respond on the basis of a single hypothesis possibly because he used some other response rule.

Size of hypothesis set. The collection of hypotheses that S considers to be potentially relevant at any given time will be called his hypothesis set. This set does not include values from a dimension that has been ignored or forgotten. The SC tests reveal directly the contents of the hypothesis set at each point in the problem, and it is a simple matter to count the number of hypotheses. Figure 2 shows the mean number of cues in the hypothesis set for the best and poorest Ss following positive and negative feedback on each FT. On average, the poorest Ss started with fewer hypotheses in their sets, but were less successful in eliminating hypotheses than were the best Ss. The size of the hypothesis set was independent of the kind of feedback, in opposition to theories which assume that resampling is more likely to occur or will always occur following an error. It might be noted, however, that Ss in the present study were highly experienced.

Distributions of processing errors. An S who processes all information perfectly will start with 8 hypotheses after FT_1 and will eliminate all hypotheses which are not consistent with new information presented with each subsequent FT. As described in Table 1, there are 8 types of possible processing errors. Distributions of errors from each S as a function of positive or negative feedback on the preceding FT are shown in Table 3, with Ss arranged in descending order of success in solving the problems.

Overall, processing errors were more likely to follow negative feedback than positive feedback, $z = 4.06$, $p < .001$. This may appear to be consistent with many information-processing theories of CI which assume that most or all processing errors occur following negative feedback (cf. Chumbley, 1969; Trabasso & Bower, 1968). However, the large proportion of errors following positive feedback (.447) must be considered evidence counter to these theories.

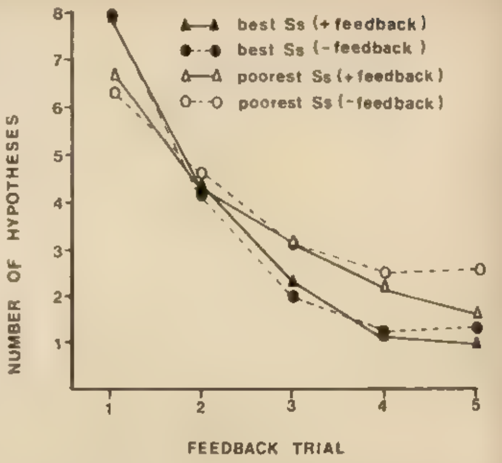

FIGURE 2. Size of the hypothesis set as a function of feedback trial number and feedback for the best and poorest Ss.

Strategies of individual Ss and departures from perfect processing can be identified from the distributions of errors. A particularly straightforward example is S_{24}, the last S in Table 3. His protocol clearly shows that he reduced his hypothesis set size to an average of 2 hypotheses at the beginning of the problems, and then used a strategy which required at least local consistency on resampling following errors. This S produced a total of 48 initial-omission errors on the 8 SC problems, for an average of 6 of these errors per problem. Since there were 8 dimensions in these problems and he eliminated an average of 6, S_{24} was tracking an average of only 2 of 8 dimensions following FT_1. This analysis was verified by a verbal report at the end of the experiment. When asked how he proceeded in his attempt to solve the problems, this S said he always started "with 1 or 2 parts." Most of the rest of the errors made by S_{24} were resampling cues which had previously been eliminated. These almost always followed only trials with negative feedback, as would be expected from an S who resamples only when the hypothesis he had been tracking was shown to be incorrect. The hypotheses he

[a] Ss are arranged in descending order (1-24) of success in solving problems.

selected for his new hypothesis set were always consistent with the last feedback (no inconsistent-resampling errors). This is the "local consistency" strategy as described by Gregg and Simon (1967).

An *S* who used a selection strategy (cf. Restle, 1962) would select a subset of possible hypotheses following FT_1, producing many initial-omission errors. Only six *S*s had over 5 initial-omission errors, but these 6 *S*s produced 8–48 each (Table 3). Judging from the scarcity of initial-omission errors in the remaining protocols, the most popular initial strategy was a "global" strategy (cf. Bruner et al., 1956), which requires *S* to process information on all dimensions simultaneously. Although the best *S*s used this strategy with considerable success, the poorer *S*s were overextended and generally made many premature-elimination and failure-to-eliminate errors.

It is apparent, however, that no *S* performed perfectly in accord with any current CI model. Failure to predict error protocols in detail is not surprising in that models typically do not include mechanisms to account for departures from idealized protocols. Such a mechanism is suggested by the current data and could be included in any model.

The random-reversal assumption. Information held by *S*s attempting to solve a CI problem may be considered in 3 parts: classification of a given dimension before an FT, cue value and feedback received from the FT, and classification of the dimension following the FT. The random-reversal assumption states that there is a small probability that information at any of these 3 steps may be lost or reversed. An alternative, suggested by Falmagne's (1972) model, is that *S* has a confidence hierarchy for the information he holds on the various dimensions, and the probability of information loss or reversal on a dimension is inversely related to the confidence.

The consequences of information loss or reversal at any 1 of the 3 steps may be examined with reference to Table 1. Reversal of the classification before an FT can lead to 1 of 2 types of errors, depending on subsequent feedback: If the feedback is consistent with the new (reversed) classification, the error will be consistency reversal; if the feedback is inconsistent with the reversed classification, the error will be premature elimination. Reversal of the classification following FT_1 leads to an initial-reversal error; reversal following a subsequent FT leads to an inconsistency-reversal error.

Perhaps the most interesting predictions of the random-reversal assumption concern the consequences of reversal of information presented on an FT. If the information is changed to be consistent with the previous classification, the error will be failure to eliminate; if the information is changed to be inconsistent with the previous classification, the error will be premature elimination. These 2 types of errors were by far the most common; together, they accounted for almost half of the total errors (Table 3).

Reversal of information could be due to incorrect encoding of the cue value or of the feedback direction; it could indicate a logical error in combining new information with old, or a memory failure followed by an incorrect guess. Any of these errors would contribute to degradation of ideal performance predicted by a simple model.

An initial-omission error is probably less an error than the result of a decision to process fewer than the total number of available dimensions. Since *S*s differ widely on this strategy (Table 3), it may be necessary to include initial sample set size as a parameter in CI models.

The SC procedure on highly trained individual *S*s was successful in providing direct evidence on a number of processing errors that have relevance to the kind of information-processing strategy that *S*s use in selecting and testing hypotheses in inductive reasoning such as CI. The present analysis has shown that individual *S*s might exhibit any of several alternative strategies, each of which is formalized in particular assumptions of existing models. In a sense, no model is entirely correct or wrong, since some protocols favor or contradict each model in turn. What appears to be lacking in the models are mechanisms such as forgetting or reversing information

so that the idealized or formal strategies are not consistently exhibited. The present experiments and specific information-processing model indicated what erroneous behavior occurs and which mechanisms seem to be responsible for the departures from perfect or consistent processing.

ABSTRACT CONCEPT LEARNING IN THE PIGEON [1]

THOMAS ZENTALL [2] AND DAVID HOGAN

University of Pittsburgh

In 1961, Cumming and Berryman found that color matching-to-sample training with pigeons did not transfer to a new color. In Experiment I in the present study, pigeons were trained on either a 2-color matching-to-sample task or a 2-color oddity-from-sample task. In the transfer phase, the 2 training colors were replaced by 2 novel colors for all *S*s and half of each training group was shifted to the other task. Nonshifted *S*s learned the transfer tasks faster than shifted *S*s. In Experiment II, using the same design, similar results were obtained when *S*s were trained on either brightness matching or brightness oddity and transferred to color matching or color oddity. Apparently pigeons are capable of learning the concepts *same* and/or *different*.

In a now classic experiment Herrnstein and Loveland (1964) demonstrated that pigeons could learn to discriminate between the presence of a human form (positive stimulus) and its absence (negative stimulus) thus suggesting that pigeons are capable of learning complex concepts. Since a large number of quite different complex visual images (photographs of natural settings) were used in both the positive and negative set, the task could not have been mastered by learning a response to each of the individual stimuli. It is less clear, however, that there was not some common attribute, other than the concept "person-present," which served to distinguish the positive from the negative set. While there was no attempt to equate the positive and negative sets in all other respects, the authors were aware of this problem. For example, to show that color distribution was not the basis for the discrimination, they presented black-and-white photographs, with little disruption in discrimination. Siegel and Honig (1970) and Poole and Lander (1971) extended these findings and ruled out a number of other artifactual cues upon which the discrimination might have been made. But, given the complexity of the stimuli used in all 3 experiments, the adequate test for, or control of, all factors other than person-present, may be virtually impossible.

A more efficient means of measuring concept learning in pigeons is with the use of simple stimuli which vary along a single physical dimension and a concept which involves the relation among these stimuli. The matching-to-sample task potentially satisfies these conditions.

In a matching-to-sample task an organism is presented with a sample stimulus and 2 or more comparison stimuli. The task requires the selection of that comparison stimulus which is the same as (matches) the sample stimulus.

Cumming and Berryman (1961) trained pigeons on a 3-color matching-to-sample task (red, green, and blue). Responses to the sample stimulus which was presented on the center response key produced the 2 comparison stimuli, one on each side key. A response to the comparison stimulus which matched the sample was reinforced.

At least 3 different means of learning this task can be described. (*a*) Pigeons may learn to make a particular response to each different stimulus configuration (e.g., peck the left key when presented

[1] This research was supported in part by Biomedical Sciences Support Grant FR7084 from the National Institutes of Health to the University of Pittsburgh and by National Institute of Mental Health Grant MH19757 to the first author. Portions of Experiment I were reported at the meeting of the Psychonomic Society, St. Louis, 1971. The authors are grateful to Celeste Compomizzi, Karen Compomizzi, Patricia Hughes, and Nancy Threlfall for their assistance with experimental sessions.

with the stimulus configuration, red–left, red–center, green–right). With 3 sample stimuli the pigeons would learn to respond individually to the 12 different stimulus configurations. (*b*) Pigeons may learn to form a response chain, one for each of the 3 sample stimuli (e.g., peck red on the center then peck red on the side). (*c*) Pigeons may learn a matching concept (i.e., peck that comparison stimulus which is the same as the center stimulus).

In an effort to determine what was learned during matching training, Cumming and Berryman (1961) substituted yellow stimuli for the blue stimuli. They found that performance was disrupted (dropped to chance) only on trials involving a yellow sample stimulus, thus suggesting that the pigeons learned response chains. The pigeons responded appropriately to red and green sample stimuli but, since they had not learned a response chain for yellow, they performed at chance when yellow was the sample. Cumming and Berryman concluded that matching training did not result in the formation of a matching concept. However, an alternative interpretation can be stated. If in fact there were competing response tendencies on yellow-sample trials, (*a*) to respond to that stimulus which had been reinforced in the past (i.e., the nonmatching red or green stimulus), and (*b*) to respond to the stimulus which matched the sample stimulus (i.e., the matching yellow stimulus), then performance may have reverted to chance, either because the pigeons alternated between the 2 response tendencies or, more likely, because the pigeons, under conflict, adopted position-response tendencies.

The purpose of the present experiments was to determine whether pigeons can acquire a matching (and/or oddity) concept if transfer involved only novel stimuli. Experiment I examined the extent to which color matching and oddity would transfer to novel colors. Since such transfer might be explained by simple stimulus generalization, rather than complex concept learning, Experiment II measured the extent to which matching and oddity training would transfer to stimuli not falling on the dimension used during training. To control for nonspecific transfer effects half of the *Ss* were initially trained on an oddity-from-sample task and shifted to the matching task with the novel stimuli. In the oddity task a response to the comparison stimulus which is *different* from the sample stimulus, is reinforced. Thus, learning an oddity concept should *retard* learning a matching task with new stimuli, and learning a matching concept should *facilitate* learning a matching task with new stimuli. Similarly, learning an oddity concept should facilitate learning an oddity task with new stimuli, and learning a matching task should retard learning an oddity task with new stimuli. Experiment I involved 4 groups of *Ss*. Two groups were trained on a 2-color matching task, and one of these was transferred to another matching task, while the second was transferred to an oddity task. Similarly, 2 groups were trained on a 2-color oddity task; 1 group was transferred to another oddity task and the second was transferred to a matching task. The transfer task involved 2 novel colors and transfer sessions were continued to assess learning.

Experiment I

Method

Subjects. Eight experimentally naive female white Carneaux pigeons approximately 1 yr. old, were maintained at 80% of their free-feeding weights throughout the experiment.

Apparatus. A standard 3-key Lehigh Valley Electronics Pigeon Test Chamber (1519D) was used. In-line projectors behind each key (with G. E. No. 1820 lamps) projected red (Kodak Wratten filter No. 26), green (Kodak Wratten filter No. 60), blue (Kodak Wratten filter No. 38A), or yellow (Kodak Wratten filter No. 9) fields onto each of the keys. Control equipment was located in the next room. Reinforcement consisted of 3-sec. access to Purina Pigeon Grains.

Procedure. All *Ss* were magazine trained and shaped to peck a lighted side key on the first day. Shaping position (left or right) and color (red or green) were counterbalanced over *Ss*. On the second day, all *Ss* were given 48 continuous reinforcements for responding to a single lighted key which varied in color (red or green) and/or position (left or right) following each reinforcement. On the third day, half of the *Ss* received matching

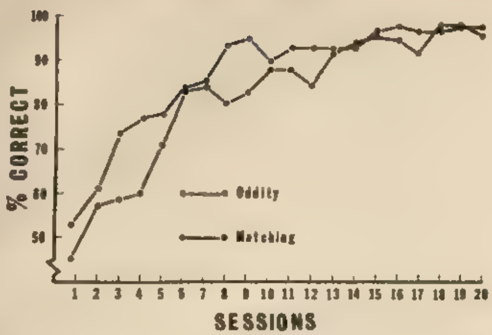

FIGURE 1. Comparison of matching and oddity performance during training: Experiment I.

training while the other half received oddity training. Each trial started with the onset of the sample stimulus on the center key. Five responses to the center key turned on the side keys. A single response to either side key terminated the trial and initiated a 5-sec. intertrial interval. Stimulus presentations for the 2 tasks were the same, only the "correct" response differed. Daily sessions consisted of 96 trials, counterbalanced for correct color and correct side. Twenty such training sessions were given.

Transfer sessions began following the last day of training. All *S*s were switched from red and green stimuli to yellow and blue stimuli. Half of the *S*s continued with the same task as during training (matching or oddity) while the remaining *S*s were shifted to the other task. Eleven transfer sessions were run

Results

Training performance data are presented in Figure 1. The data suggest that the oddity task was learned faster than the matching task, though this difference was significant only on the first session, $F(1, 6) = 6.40$, $p < .05$. On the first session, 3 of the 4 oddity *S*s performed above chance while 3 of the 4 matching *S*s performed *below* chance. By the end of training no difference in performance between the 2 groups was apparent.

The transfer data are presented in Figure 2. The nonshifted *S*s were those for which the training task and transfer task were the same; for the shifted *S*s the training task and transfer task differed. A 2-way analysis of performance on the first transfer session indicated a nonsignificant training effect (matching vs. oddity) ($F < 1$), a nonsignificant transfer effect (matching vs. oddity) ($F < 1$), and a nonsignificant Training × Transfer interaction (shifted vs. nonshifted), $F(1, 4) = 2.41$, $p > .05$.

The nonsignificant difference between shifted and nonshifted *S*s on the first transfer session may be due to the fact that 4 of the 8 *S*s were correct on exactly half of the trials. For the 4 birds whose performance differed from chance, however (1 shifted *S* and 3 nonshifted *S*s), performance of the shifted *S* was below that of the 3 nonshifted *S*s. A second 2-way analysis of performance pooled over the first 5 transfer sessions indicated a nonsignificant training effect ($F < 1$) and a nonsignificant transfer effect, $F(1, 4) = 1.80$, $p > .05$, but a significant Training × Transfer interaction, $F(1, 4) = 7.89$, $p < .05$. The interaction indicates that nonshifted *S*s performed significantly better over the first 5 transfer sessions than did the shifted *S*s.

Experiment II

Using the same design as in Experiment I, *S*s were trained on either a matching or oddity task with 4 sample brightnesses. Four brightnesses were used to

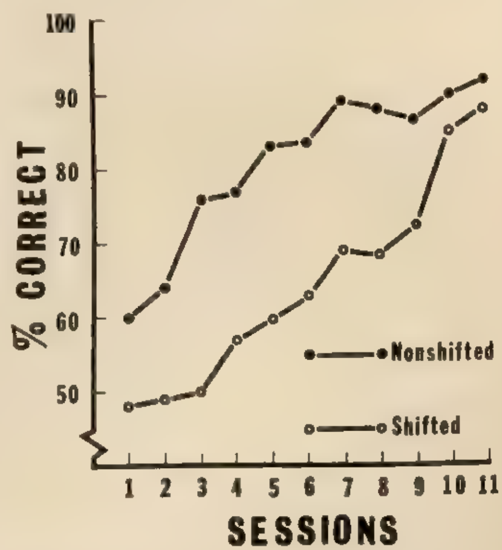

FIGURE 2. Experiment I transfer data. (Shifted *S*s are those transferred to a new concept—matching to oddity or oddity to matching; nonshifted *S*s are those maintained on the same concept—matching to matching or oddity to oddity.)

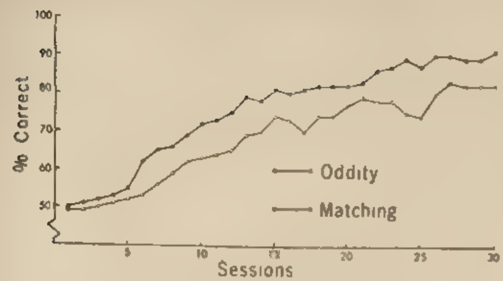

FIGURE 3. Comparison of matching and oddity performance during training: Experiment II.

maximize the likelihood that a matching and/or oddity concept would be formed. All *S*s were then transferred to 2 colors with half of the *S*s shifted in concept and the other half nonshifted.

Method

Subjects. Twelve experimentally naive female loft-reared pigeons approximately 1 yr. old were maintained at 80% of their free-feeding weights throughout the experiment.

Apparatus. The apparatus was the same as that used in Experiment I. The training stimuli were obtained by lighting 10 unfiltered lamps (G. E. No. 1820, supplied by 24 v.), 1 unfiltered lamp, 1 lamp with a 1.0 neutral density Kodak Wratten filter, or 1 lamp with a 2.0 neutral density Kodak Wratten filter. The brightness values were 13.0, 3.00, .30, and .03 ftc. as measured by a United Detector Technology Opto-meter (Model 40A) with a photome ric filter having transmission characteristics approximating the spectral sensitivity of the human eye. It should be noted that spectral sensitivity in pigeons is quite similar to that in humans (Blough, 1957).

The transfer stimuli were the red and green values used in Experiment I equated for brightness at 1.0 ftc. All brightness values were checked at the end of the experiment and were found to be consistent with initial measurement.

Procedure. On the first day, each *S* was shaped to peck either the right or left response key illuminated with 1 of the 4 brightness values. Shaping stimuli were assigned to *S*s such that, when *S*s were divided into 2 groups, 3 from each group had been shaped to the left and 3 to the right. Within each of the 2 groups 1 *S* had been shaped to the brightest stimulus value, 1 *S* to the dimmest stimulus value, and 2 *S*s each to the 2 middle stimulus values.

On the second day, all *S*s were given 48 continuous reinforcements for responding to a single lighted key which varied in brightness and/or position (left or right) following each reinforcement. On the third day, half of the *S*s received matching training while the other half received oddity training. perior to performance on the matching task. The Training × Transfer interaction indicates better performance for nonshifted *S*s than for shifted *S*s. A similar analysis of the Session 2 data indicated nonsignificant effects of training ($F < 1$), transfer, $F\ (1, 8) = 1.98$, and Training × Transfer interaction ($F < 1$). By the second transfer session, all but 1 *S* were performing above chance, and by Session 6 mean performance was above 95% correct. A 2-way analysis of the transfer data pooled over days indicated nonsignificant effects of training ($F < 1$), transfer, $F\ (1, 8) = 3.67$, $p > .05$, and Training × Transfer interaction ($F < 1$).

A 2-way analysis using sessions-to-criterion (90% correct) indicated similar results, though the transfer effect was significant, $F\ (1, 8) = 5.60$, $p < .05$, with this measure. Thus, for the transfer task, oddity was apparently learned faster than matching.

Discussion

The results of Experiment I indicate that matching and oddity training with pigeons will transfer better to new stimuli when the transfer task is the same as the training task than when the transfer and training tasks are different. The results of Experiment II indicate that these effects can be observed under conditions where generalization along a stimulus continuum (e.g., wavelength) cannot account for the transfer difference. The data suggest that the concepts *same* and/or *different* can be learned when pigeons master matching and oddity tasks, respectively. While the present design does not allow for the evaluation of these concepts separately, it does offer presumptive evidence for some form of "abstract" concept learning in pigeons. The word *abstract* is used here to identify transfer which cannot be explained by (*a*) stimulus generalization along physically definable dimensions or (*b*) nonspecific transfer effects.

While Experiments I and II are in basic agreement with regard to the transfer of concept learning, certain differences in the obtained results should be discussed.

During original training in Experiment I oddity performance was superior to matching performance for the first training session. In Experiment II there was vitually no difference between matching and oddity performance on the first training session, though over sessions superior performance was found on the matching task. These results are not inconsistent with the results of other studies which have reported comparisons of matching and oddity training.

Using a very lax criterion for learning (16 out of 20 correct), Ginsburg (1957) found that pigeons learned an oddity task faster than a matching task. Berryman, Cumming, Cohen, and Johnson (1965) found that performance on an oddity task was initially superior to performance on a matching task, but after about 600 training trials a crossover occurred and matching performance continued to be superior from then on. Both studies used 3 different sample stimuli for both matching and oddity. While oddity performance may be initially better than matching, the data suggest that matching may be learned faster when a moderate to stringent learning criterion is used.

Initial superiority of birds trained on the oddity task (Experiment I in this study; see, also, Berryman et al., 1965; Ginsburg, 1957) may be due to an artifact of pretraining. Typically, pretraining consists of single-stimulus presentation of each of the 3 keys (only 2 keys in the present studies). Then, at the start of training the center key is illuminated and responses to it illuminate the side keys, but for the first time these responses are not reinforced. It was observed in the present studies that during early training trials as many as 100 center key pecks occurred before a response was made to either side key (which terminated the trial). Undoubtedly, these nonreinforced pecks served to partially extinguish responding to the center key, and it is reasonable to expect that this partial extinction generalized to the same stimulus on the side key. Thus, better than chance performance on the oddity task can occur without any specific oddity training.

During training in Experiment II the failure to observe initial superiority of oddity over matching may be due to the specific training stimuli used. It may be that the brightness differences in Experiment II were not as salient as the color differences in Experiment I, and thus, initial extinction to the stimulus on the center key generalized nearly equally to the 2 comparison stimuli in Experiment II.

The superiority of matching later in training suggests that in addition to whatever concept

learning occurs, pigeons master matching and oddity by learning response chains (e.g., peck red on the center then peck red on the side). The fewer response chains to be learned the easier the task. In general, with n different sample stimuli, matching requires learning n response chains (one for each sample stimulus). Oddity, however, requires learning $n(n-1)$ response chains (a separate chain for each sample stimulus combined with each possible odd stimulus). With 2 sample stimuli, $n = 2$ and $n = n\ (n-1)$, matching and oddity should not differ in difficulty. Experiment I of the present study confirms this prediction. With 3 or more stimuli, $n < n\ (n-1)$ and matching should be easier than oddity. Berryman et al. (1965) and Experiment II of the present study confirm this prediction. Unfortunately the above model is insufficient to account for superior oddity learning (sessions to criterion) during transfer sessions in Experiment II. Other factors apparently contribute to the relative speeds of matching and oddity learning.

A second difference between the results of Experiments I and II was the occasion of the appearance of the concept–transfer effect. In Experiment I a significant transfer effect appeared only after the first transfer session; in Experiment II the same effect was significant only *on* the first transfer session. The difference in transfer results between the 2 experiments was probably due to the difference in transfer stimuli (yellow and blue in Experiment I; red and green in Experiment II), though it is possible that differences in either *S* pool (strain differences) or differences in original training, i.e., training stimuli (colors in Experiment I and brightness values in Experiment II), number of training stimuli (2 in Experiment I and 4 in Experiment II), and number of training sessions (20 in Experiment I and 30 in Experiment II) may have affected the transfer results as well. The fact that 2 *S*s in Experiment I responded to the yellow comparison stimulus on every trial of the first transfer session, while no *S* in Experiment II showed a complete color preference, suggests that differences in transfer stimuli may have been responsible for the observed differences in transfer results.

DYNAMIC PROCESSES IN STIMULUS INTEGRATION THEORY: EFFECTS OF FEEDBACK ON AVERAGING OF MOTOR MOVEMENTS[1]

KENT L. NORMAN[2]

University of California, San Diego

A stimulus integration experiment was conducted which provided feedback to *S* in a task requiring the averaging of 2 fixed-movement lengths. Feedback indicated the relative position of each response to a weighted average of the lengths. Changes in the integration rule as a function of feedback were indicated by changes in the weighting parameters of a general weighted average model. Feedback appropriate to the numerical average reduced an initial bias toward the longer distance, while no changes were noted for a group that received no feedback. When feedback placed greater weight on the longer or shorter movement in a pair, systematic changes were observed in *S*s' responses, but not when feedback placed greater weight on the movement in the first or second ordinal position. These results indicate that in some cases the integration rule may be a function of dynamic processes such as feedback.

A judgment may be viewed as a response dependent on a set of stimuli, and the observer, an integrator of stimulus information. Stimulus integration theory and functional measurement proposed by Anderson (1962, 1970) has studied integration behavior in a number of tasks. The primary assumption of this theory is that the judgment is an algebraic function of the subjective stimulus values, s, and weights, w, on the subjective stimulus values.

While the observer may be viewed as an integrator of information, it must also be remembered that he is an organism capable of learning, and that the judgment response may also be a function of practice and feedback. It is likely that such feedback affects the integration function. Slovic and Lichtenstein (1972) pointed out that little or no research has been done on learning to integrate stimuli and on the effect of feedback in stimulus integration paradigms. However, experimentation on dynamic processes has been conducted in Bayesian decision-making and multiple-cue learning tasks. Methodologically, integration theory has an advantage over correlational paradigms in that it uses subjective scale values rather than physical values. Other advantages have been discussed elsewhere (Anderson, 1962, 1972).

The present research is an attempt to extend the investigation of the effects of feedback and dynamic processes to an integration task involving the averaging of motor movements. The *S*s were blindfolded and required to make several successive controlled motor movements and then make an additional linear movement to represent the average of the previous fixed movements. This task has been studied by Levin, Craft, and Norman (1971) and by Levin, Norman, and Dolezal (1973). These authors noted that a possible advantage that this task may have over other integration tasks is that stimulus magnitude is manipulated along a continuous dimension and responses are executed along the same dimension.

Levin et al. (1971) found that the data could be approximated by an ordinal-

[1] This project was supported during the author's tenure in the U.S. Public Health Service predoctoral fellowship, National Institute of Mental Health, under Grant MH-51134-01, and completed while a visitor at the Center for Human Information Processing, University of California, San Diego, under Grant MH-15828 from the National Institute of Mental Health. The report is based on a dissertation submitted in partial fulfillment of the requirements for the PhD degree at the University of Iowa. Appreciation is expressed to the chairman, Irwin P. Levin, and members of the dissertation committee, Donald D. Dorfman, James V. Hinrichs, Raymond H. Hohle, and Rudolph W. Schulz, for their many helpful comments.

dependent weighted average model,

$$R_A = \sum w_i s_i, \qquad [1]$$

where R_A is the averaging response, w_i is the weight varying with ordinal position on the subjective value s_i, such that $\sum w_i = 1$. However, there was a significant interaction between stimulus levels that could not be accounted for with an averaging model with constant weights. Levin et al. (1973) confirmed that the interaction between stimuli within a set was highly reliable. Since the response scale appeared reliable, a different averaging model was proposed that weighted stimuli differentially as a function of their value. This model can be expressed as

$$R_{ij} = \frac{v_i s_i + v_j s_j}{v_i + v_j}, \qquad [2]$$

where R_{ij} is the magnitude of the averaging response for stimuli i and j, and where v_i and v_j refer to weights on the subjective stimulus values varying with the values of the stimuli. Furthermore, the restriction is added that the weights sum to 1. The fact that both order-dependent weighting and value-dependent weighting may be present in this motor task make it an ideal one to study.

The following 3 issues relating to the effect of feedback on the integration rule were investigated in the present study: (*a*) effects of "correct" numerical feedback vs. no feedback, (*b*) effects of feedback on order-dependent weighting, and (*c*) effects of feedback on value-dependent weighting. These effects may be localized in the accuracy of the subjective scale values or in changes in weight parameters.

One group was given correct feedback using the numerical average (NA) and another group was given no feedback (NF). A comparison of these groups should indicate fundamental differences between feedback and no-feedback conditions. Furthermore, these groups are necessary control conditions for other groups.

In a second comparison, one group was given feedback with respect to a primacy weighted average (PWF) and another group was given feedback with respect to a recency weighted average (RWF). Since *S*s averaged only pairs of distances, a primacy effect is defined as greater weighting on the first stimulus and a recency effect is defined as greater weighting on the second stimulus. The ratio of the order-dependent weights on the feedback trials was set at 2:1 for Group PWF and 1:2 for Group RWF, according to the model in Equation 1. The observed weights may be compared on both feedback and test trials.

In a third comparison, feedback from a value-dependent weighted average was provided where longer distances received greater weight for one group (Group LWF) and where shorter distances received greater weight for another group (Group SWF).

Since the results of the 3 experimental manipulations may follow either an order-dependent weighted average or a value-dependent weighted average model, some procedure is needed to test the specific form of the model. One procedure is to use a general model that includes the other models as special cases. Then the specific models can be statistically compared with the general model. A general model which includes the order-dependent weighted average model, the value-dependent weighted average model, and the simple numerical average model as special cases is

$$R_{ij} = \frac{w v_i s_i + (1 - w) v_j s_j}{w v_i + (1 - w) v_j}, \qquad [3]$$

where w is a weight applied to the first stimulus in the pair, $1 - w$ is a weight applied to the second stimulus in the pair, and v_i is the weight component for the scale value s_i. The sum of all value-dependent weight components is set equal to 1. If the order-dependent weights are equal, Equation 3 reduces to a value-dependent weighted average model; and if the value-dependent weights are equal, it reduces to an order-dependent weighted average model. If both sets of weights are equal, it reduces to a simple numerical average.

Method

Design

The *S*s produced averages of pairs of fixed movements (stimuli, S_1, S_2), where each length was 20, 40, or 60 cm. during pre- and postfeedback trials

Note. Abbreviations: NA = numerical average, PWF = primacy weighted average, RWF = recency weighted average, SWF = shorter distances receiving greater weight, LWF = longer distances receiving greater weight, S_1 = stimulus of first distance, S_2 = stimulus of a second distance, and 15, 30, and 45 refer to distances in centimeters.

and 15, 30, or 45 cm. during feedback trials. All 9 pair combinations were repeated 3 times in a randomized blocks presentation to obtain prefeedback baseline data. Four randomized blocks of the 9 pair combinations were presented for feedback trials and 3 blocks for postfeedback trials.

During feedback trials, *S*s were told the distance (rounded off to the nearest centimeter) that each response was over or under the average, according to the prescribed model. Feedback given was appropriate to the numerical average for Group NA, a primacy weighted average where $w = 2/3$ for Group PWF, a recency weighted average where $w = 1/3$ for Group RWF, and a value-dependent weighted average (see Equation 2) where $v_{15} = 1/2$, $v_{30} = 1/3$, and $v_{45} = 1/6$ for Group SWF, and where $v_{15} = 1/6$, $v_{30} = 1/3$, and $v_{45} = 1/2$ for Group LWF. The prescribed averages for each condition are listed in Table 1. Group NF produced averages during this stage, but received no feedback.

Apparatus

The apparatus was the same as that used by Levin et al. (1971). Two free-moving, 5-cm.-sq. Plexiglas blocks were mounted on a wooden meter stick. The right-hand block could be locked in place by *E* when defining the length of the fixed movements and could be moved out of the way when *S* was making his averaging response. An additional sliding scale was added for the present experiment so that *E* could read directly the distance that *S*'s response was over or under the average prescribed by the feedback requirements. This scale was zeroed in on the prescribed average before *S* made his averaging response. The apparatus was placed on a table parallel to the coronal plane, and a shield was placed over the meter stick. The *S* was blindfolded so that responding could not be based on visual cues.

Procedure

On each trial, *S* was required to complete the fixed movements S_1 and S_2 and then move the sliding block a distance which he estimated to be the average of the 2 fixed movements. Details of this procedure are given by Levin et al. (1971). The time to complete each fixed movement and return to the starting position was approximately 8 sec. Five seconds were allowed for *S* to produce the average before he was to hold the block steady so that the distance could be read and the feedback given during the feedback trials. Responses were recorded to the nearest millimeter. The distance (rounded off to the nearest centimeter) over or under the prescribed average was then read off by *E*. For example, if the prescribed average was 37.5 cm. and the response was 40.1, *S* heard "over by 3 cm." The interval between trials was 5 sec.

During the feedback trials, *S* was told that he would learn a new type of average that might or might not differ from the "regular" average. This new average was called the "navigational average." The *S* was instructed to use this feedback to influence his subsequent responses so that he could "home in on navigational averages." Two 5-min. breaks were inserted—one following prefeedback trials and one following feedback trials. Finally, a short questionnaire was administered. The *S*s were asked to explain in their own words what the navigational average was, how they made the averages, and if they used any special strategy.

Subjects. Each of the 6 groups was composed of 10 *S*s (5 female and 5 male) recruited from introductory psychology classes at the University of Iowa.

Results

The mean averaging responses on the pre- and postfeedback trials are graphed in the successive panels of Figure 1 for each group.

All main effects of S_1 and S_2 were highly significant for all groups at all stages. The steepness of the lines reflects the effect or weighting of S_2 in determining the average, and the degree of separation of the lines reflects the effect or weighting of S_1. Deviations from parallelism indicate the extent of value-dependent weighting. Lines that converge with increased stimulus magni-

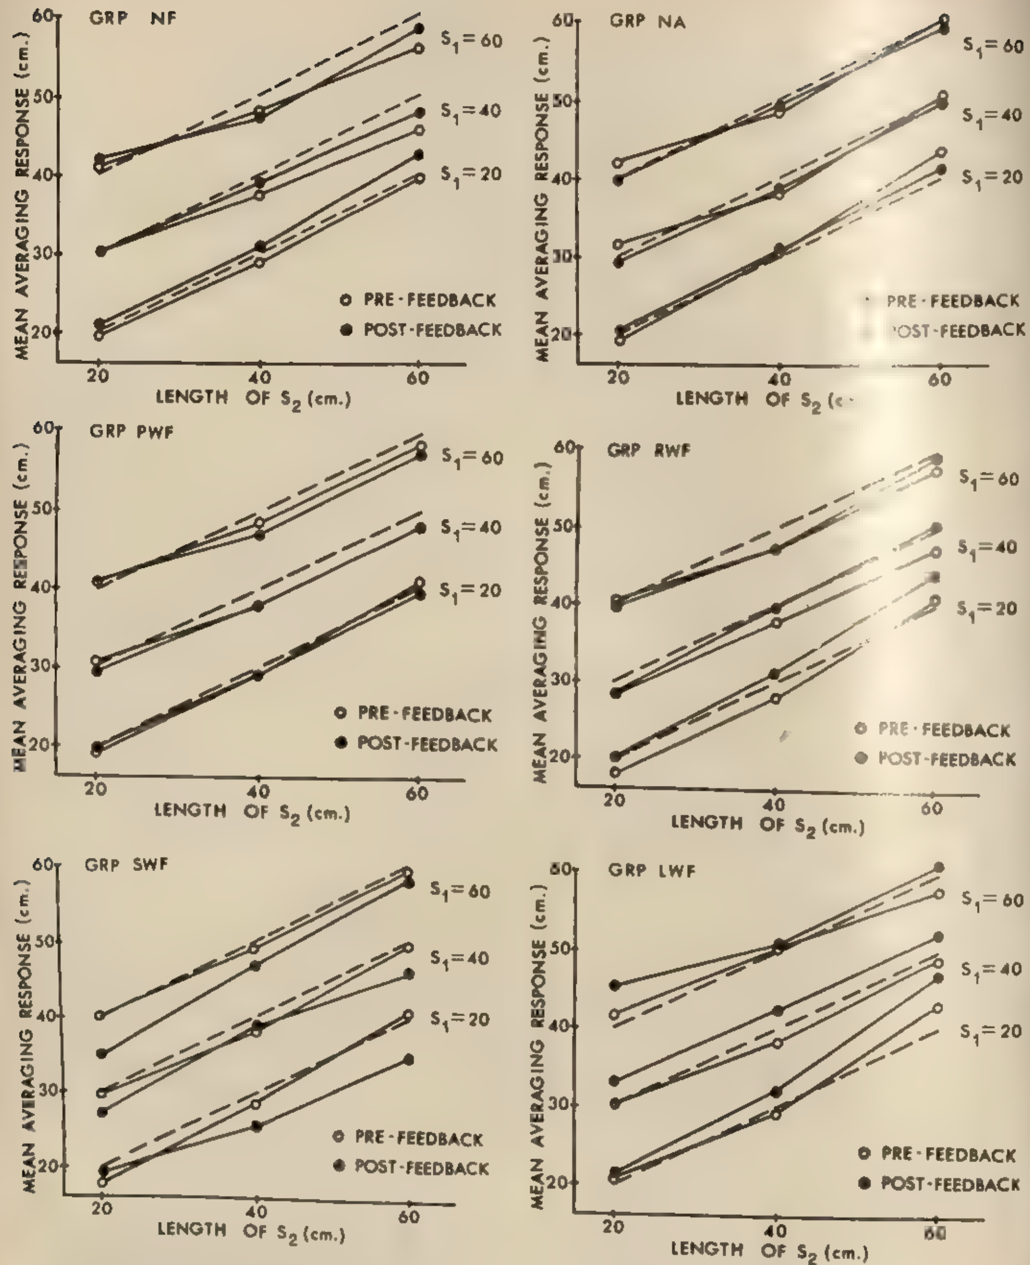

FIGURE 1. Mean averaging responses on pre- and postfeedback trials as a function of the magnitude of the stimuli (S_1 and S_2) for each group. (Dotted lines indicate physical means. Abbreviations: NF = no feedback, NA = numerical average, PWF = primacy weighted average, RWF = recency weighted average, SWF = shorter distance receiving greater weight, and LWF = longer distance receiving greater weight.)

tude imply a greater weighting of longer distances, and lines that diverge with increased stimulus magnitude imply a greater weighting of shorter distances.

Prefeedback Trials

On prefeedback trials, a very slight converging interaction can be noted for most of the groups. The difference between the

pairs 60–20 cm. and 60–60 cm. is less than the difference between 20–20 cm. and 20–60 cm. The form of this interaction is consistent with the interpretation that longer distances received greater weighting. When prefeedback trials were analyzed for initial group differences, all between-groups effects were nonsignificant. The $S_1 \times S_2$ interaction was highly significant, F (4, 216) = 22.52, $p < .001$. Furthermore, this interaction occurred in a large majority of the individual *S* analyses.

Learning Curves on Feedback Trials

Learning curves were constructed for the 4 feedback blocks on Stage 2. Mean absolute error with respect to the average designated as correct was used as an overall measure of learning for the feedback groups. For Group NF, mean absolute error was taken with respect to the numerical average. Figure 2 shows these curves. No systematic changes occurred for Groups NF or NA, through NA tended to be more accurate than NF. No decrease occurred for Groups PWF or RWF; however, mean absolute error for Groups SWF and LWF showed trends to decrease with blocks of trials. With mean absolute error as the dependent variable, the blocks effect was significant for Group LWF, F (3, 27) = 3.72, $p < .05$, but not for Group SWF. It should be noted that it is not at all clear that performance stabilized by the end of the feedback stage. This fact limits the interpretation of data on the postfeedback trials to the levels of learning evidenced on the feedback trials.

Postfeedback Trials

Responses for Group NF did not change from pre- to postfeedback trials. For Group NA, the converging $S_1 \times S_2$ interaction observed on prefeedback trials did not occur on postfeedback trials. This change would be expected due to feedback.

No significant changes occurred on the postfeedback stage for Group PWF. Had *S*s learned and used the primacy weighted average on postfeedback trials, the effect of S_1 should have increased from pre- to postfeedback trials and the effects of S_2 should have decreased. This did not happen. Similarly, for Group RWF, if *S*s used a recency weighted average on postfeedback trials, the effect of S_2 would have increased and the effect of S_1 would have decreased from pre- to postfeedback trials. Though there were trends in these directions, they were not significant. A post hoc analysis for Group RWF compared the mean of the pairs 20–40 cm., 20–60 cm., and 40–60 cm. with the mean of the pairs 40–20 cm., 60–20 cm., and 60–40 cm. The mean of the former pairs was greater than the mean of the latter, indicating recency, t (9) = 2.31, $p < .05$. However, only 2 of the 10 *S*s showed marked effects in the predicted direction.

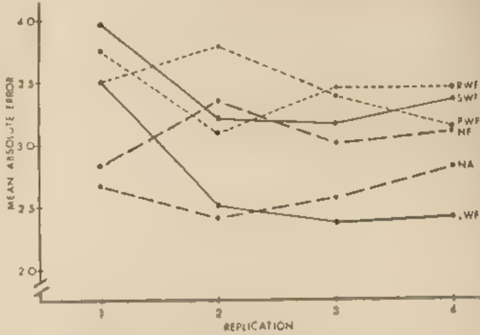

FIGURE 2. Mean absolute error as a function of replications of control trials for the no-feedback (NF) group and replications of feedback trials for the following groups: numerical average (NA), primacy weighted average (PWF), recency weighted average (RWF), shorter distance receiving greater weight (SWF), and longer distance receiving greater weight (LWF).

As seen in the Group SWF panel in Figure 1, a large interaction occurred on postfeedback trials. The form of this interaction differs from the converging interaction noted on prefeedback trials. The lines tend to diverge as stimulus magnitude increases. This interaction is consistent with an integration model that weights shorter distances more than longer distances. The 3-way $S_1 \times S_2 \times$ Stage interaction was highly significant, F (4, 36) = 10.89, $p < .001$. Individual *S* analyses showed that this change in the direction of the interaction occurred for most *S*s (8/10) and reached significance for 3 *S*s ($p < .05$). The overall mean averaging response de-

TABLE 2

Maximum Likelihood Ratio Tests for the General and Restricted Models

	Prefeedback all groups	Group NF	Group PWF	Group RWF	Group SWF	Group LWF

[illegible]	[illegible]	[illegible]	[illegible]	11.80	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	[illegible]	(2) 34.50	(2) 17.58	[illegible]

[illegible] square relative to the cell [illegible]. The numbers in parentheses are the degrees of freedom of each [illegible] LWF = longer distances receive [illegible] PWF = primacy weighted average, RWF = recency weighted average, [illegible] weights, and [illegible] order-dependent weight.

creased from 38.8 cm. on prefeedback trials to 36.6 cm. on postfeedback trials, $F(1, 9) = 8.93$, $p < .05$. The value-dependent weighted average model predicts that the averages of heterogeneous pairs should decrease while homogeneous pairs should remain constant from pre- to postfeedback trials. Therefore, a post hoc comparison was made on the homogeneous pairs. No change in homogeneous pairs occurred with stage, $F(1, 9) < 1$.

For Group LWF, the converging interaction increased only slightly from pre- to postfeedback trials, but this trend did not reach significance. The majority of *Ss* showed no change with stage. However, the overall mean increased from 40.0 cm. on prefeedback trials to 42.8 cm. on postfeedback trials, $F(1, 9) = 19.87$, $p < .01$. The value-dependent weighted average model with greater weight for longer distances predicts that responses to heterogeneous pairs should increase while responses to homogeneous pairs should remain the same from pre- to postfeedback trials. Again a post hoc test was made to see if any changes occurred for the homogeneous pairs alone. A significant increase was found of about the same magnitude as the overall increase (2.8 cm.), $F(1, 9) = 35.69$, $p < .001$. Thus, it appeared that feedback did not increase the value-dependent weighting of longer distances as much as it caused an increase in the absolute magnitude of the averaging response.

Model Analysis

The general model (Equation 3) provides for both value-dependent and order-dependent weighting. As noted earlier, these parameters may be systematically restricted to simplify the model. Parameter estimates for these models were obtained by the method of maximum likelihood with the assumption that observations were normally distributed with heterogeneous variances.

Given maximum likelihood estimates, the restricted models may be statistically compared to the general model by likelihood ratio tests (Kendall & Stuart, 1961). The tests for each model are not indepen-

TABLE 3

Parameter Estimates for Best Model

Parameter	Prefeedback trials (all groups)	Postfeedback trials					
		NF	NA	PWF	RWF	SWF	LWF
s_{20}	19.15	20.79	20.89	19.79	20.31	18.91	[illegible]

v_{60}	.372	.378				[illegible]	[illegible]
w					.429		
$1-w$					.571		

Note. The parameter $v_{60} = 1 - v_{20} - v_{40}$. Abbreviations: NF = no feedback, NA = numerical a[illegible], PWF = [illegible] weighted average, RWF = [illegible], SWF = [illegible] receiving greater weight, LWF = longer distances receiving greater weight, s = subjective stimulus values, v = value-dependent weight, w = order-dependent weight, and 20, 40, and 60 refer to distances in centimeters.

dent of each other. However, if all possible tests of restrictions are conducted to form a matrix of results, each restriction can be evaluated in combination with all other parameter restrictions. The likelihood function was maximized for the data collapsed over replications and groups on prefeedback trials and for the data collapsed over replications on postfeedback trials for each group.

In all cases, the general model fit the data extremely well. Theoretical means did not deviate appreciably from the observed means. Results of the likelihood ratio tests are presented in Table 2.

Prefeedback trials. The restricted model with $w = 1/2$, implying a lack of order effects, does not fit significantly worse than models including an order-dependent weight. This is indicated in Table 2 by the fact that values in the column for restricted weights are not significant relative to Column 1. However, value-dependent weights are a necessary part of the model as indicated by the large increase in cell entries from Row 1 to Row 2. Table 3 lists the parameter estimates for the most parsimonious model not significantly worse than the general model. The value-dependent weights for prefeedback trials covary with the scale values. This indicates that *Ss* weighted longer distances more than shorter distances. The theoretical means for this model did not deviate appreciably from the observed means.

Postfeedback trials. On postfeedback trials for Group NF, the simplest model was the value-dependent weighted average model since entries in Row 2 of Table 2 are much larger than Row 1. The value-dependent weights listed in Table 3 again covary with scale value. Thus, for Group NF the model did not change from pre- to postfeedback trials and the value-dependent weights remained approximately the same.

Table 2 indicates that for Group NA, both the value-dependent and order-dependent weights are not necessary assumptions for the model to fit the data. The general model does not fit significantly better than a simple numerical average model. Thus, in this group the feedback reduced value-dependent weighting and helped *Ss* to give responses appropriate to the correct numerical average. Though a change in the model from pre- to postfeedback trials occurred, the preceding analysis does not constitute a test of the significance of such a change.

Table 2 indicates that for Group PWF, as for Group NA, the simple average model fits the data no worse than the general model. Feedback did not affect order-dependent weighting as expected; hence, it was not a necessary requirement in the model. For Group RWF, large and significant entries in Table 2 in Column 2 indicate that order-dependent weighting is a necessary requirement of the model. However value-dependent weighting is not necessary. Table 3 gives the parameter estimates for this order-dependent weighted average

model. The value of w indicates that the second (most recent) stimulus received a greater weighting. Thus, the feedback apparently influenced S's responses in this group to weight the second distance more. It should be noted again that the group effect here is primarily localized in the data of a few Ss.

For Groups SWF and LWF, large entries occur in Table 2 when the value-dependent weights are constrained to be equal, but not when the order-dependent weighting is restricted. This indicates that a value-dependent weighted average model is necessary to fit the data for these groups. The value-dependent weights listed in Table 3 indicate that shorter distances received greater weighting than longer distances for Group SWF. This model is in line with the feedback given to this group and is consistent with the highly significant diverging interaction that was obtained on postfeedback trials. Unlike Group SWF, the longer distances received the greater weighting in Table 3, as prescribed by the feedback. These weights are more extreme than those on prefeedback trials, but, as noted earlier, the converging $S_1 \times S_2$ interaction did not increase significantly.

Subjective Scale Values

The subjective scale values estimated for pre- and postfeedback trials for each group are also listed in Table 3. Overall, these values are close to the physical distances although underestimation occurred for 40- and 60-cm. distances. Very little change in the scale values occurred from pre- to postfeedback trials except for Group LWF. As noted earlier, this group tended to increase all responses on postfeedback trials. This is reflected in the increased scale values for Group LWF.

All the stimulus scales, while differing slightly, should be at least linearly related for scale invariance to hold (Anderson, 1970). Likelihood ratio tests were conducted for each group comparing the hypothesis that different scales were needed for pre- and postfeedback trials with the null hypothesis that the scales were linearly related. In all cases the null hypothesis of scale invariance held as indicated by the small and nonsignificant chi-square values.

Discussion

Previous research has shown that the integration function often depends on the particular task. In most experiments, task characteristics have generally remained constant, and the integration rule that Ss use is static. Feedback characteristics had a great effect in the present study on averaging responses, and complex changes in the response pattern resulted. These results indicate that the integration rule may also be a function of feedback and practice, and that the combinatorial rule may be learned. The study of this learning process may help to (a) explain why certain integration rules are used, and (b) delineate the cognitive processes by which Ss actually combine stimuli.

As found in previous studies (Levin et al., 1971; Levin et al., 1973), no order effect obtained with only 2 stimuli on prefeedback trials. Similarly on postfeedback trials for each group except RWF, order-dependent weighting did not obtain. In Group RWF, order-dependent weights were necessary and indicated a greater weighting of the most recent stimulus as predicted by the feedback to this group. Individual S analyses, however, indicated that this effect was evidenced in only a few Ss. On prefeedback trials, value-dependent weights varied directly with stimulus magnitude. This is consistent with the form of the $S_1 \times S_2$ interaction found on these trials. On postfeedback trials, it was found that in Groups NA, PWF, and RWF, value-dependent weights could be eliminated from the model. This was not true for Groups NF, SWF, and LWF. Value-dependent weighting did not change appreciably for Group NF from pre- to postfeedback trials. For Group LWF, the weights which varied directly with stimulus magnitude became a little more extreme, while for Group SWF, the value-dependent weights changed appreciably from directly varying with stimulus magnitude on prefeedback trials to indirectly varying on postfeedback trials.

In the present experiment, one may consider the 2 distances, S_1 and S_2, to be the only stimuli that Ss integrated on each trial. In other tasks to which integration theory has been applied, such as probability learning, feedback over a number of trials constitutes the set of stimuli to be combined (e.g., Freid-

man, Carterette, & Anderson, 1968; Levin, Dulberg, Dooley, & Hinrichs, 1972). In the present task, feedback on previous trials may be viewed as yet another set of stimuli to be integrated along with S_1 and S_2. This process may take on several forms. Each averaging response is a function of S_1, S_2, and feedback on the previous trials. One model may assume that *S* integrates S_1 and S_2 as he did on the first trial and then adjusts or biases his response as a function of previous feedback. Models like this one *bias* the integrated response; they do not change the *rule* by which S_1 and S_2 are integrated.

Other models may assume that feedback alters the integration rule itself or at least the parameters in that rule. For a value-dependent weighted average model like Equation 3, the weights may be a function of feedback. These 2 types of models represent the fundamental psychological distinction between response bias and integration processes. While these 2 processes are conceptually distinct in operation, they are often confounded and inseparable. As far as the integration rule represents a cognitive process, it is encouraging when *S*s report a specific model or process that they used. This, however, does not guarantee that they did indeed use that model. Research on the specific effects of feedback may help to separate the effects of bias from the integration process.

In some cases, feedback appeared to change the form of the integration rule and not response bias when responses to different stimulus pairs changed in different ways. In Groups NA and SWF, the responses to heterogeneous pairs decreased from pre- to postfeedback trials while the responses to homogeneous pairs remained constant. On the other hand, for Group LWF, responses to both heterogeneous and homogeneous pairs increased in magnitude. Feedback affected responses to all the pairs in the same way, and the integration rule did not change substantially as a function of feedback. Feedback either tended to augment the subjective scale values or cause a bias in the response function. Such a result may be due to a possible generalization of feedback to averages of homogeneous stimulus pairs. The *S*s in Group LWF were told that they were under the prescribed average a large percentage of the time. Since initially homogeneous pairs were underestimated, *S*s may have tended to increase all averaging responses. This generalization effect did not occur for Group SWF. In this group, *S*s were almost always told that responses to heterogeneous pairs were over the prescribed average while responses to homogeneous averages were usually under because of the tendency toward underestimation.

Feedback for Groups PWF and RWF had little or no effect on changing the integration rule on the feedback trials. The number of explanations for a null effect are of course unlimited. However, one plausible hypothesis again is that feedback may have generalized between distance pairs. For example, in Group PWF, *S*s were usually told that their responses were over for the 20–60-cm. pair and under for the 60–20-cm. pair. Feedback generalization would functionally lead to the numerical average. Indeed, the pattern of responses for these 2 groups was most like that for Group NA. Several *S*s in Groups PWF and RWF reported that they thought there was a random variation in the new average they were to learn but that it was otherwise the same as the numerical average. Thus, *S*s generally did not discover that order was a relevant cue in the integration function.

Integration rules may be viewed as conceptual rules (e.g., Adams, 1953; Summers & Hammond, 1966; Uhl, 1963). Such conceptual rules are different from those that deal only with the presence or absence of discrete attributes since the components are continuous. The conceptual rule used by *S* may be modeled by a mathematical function which adequately describes the relationship between the stimulus sets and the matrix of responses. While *S*s in Group SWF clearly learned a new conceptual rule, and indicated this verbally following the experiment, *S*s in other groups did not. Similar to studies on rule learning (e.g., Conant & Trabasso, 1964; Hunt & Hovland, 1960), this evidence may indicate that some conceptual rules are learned with greater ease than others. This may be because some aspects of the stimulus set are viewed as naturally contributing to the integration rule while others are not. For example, it is very uncommon for sequential order to contribute to a measure of central tendency.

In conclusion, the present results are evidence that dynamic processes occur in stimulus integration as a function of feedback. Feedback may have a number of effects on the integration rule in terms of weighting parameters or response bias. A careful distinction must be made between the dynamic processes of response bias and integration rule learning similar to the distinction in psychophysics

between decision and sensory processes. The present study supports the notion that integration rules are concepts and as such they may be learned and modified.

VISUAL IMAGERY FOR WORDS: THE HEBB TEST[1]

ROBERT J. WEBER[2] AND ROGER HARNISH

Oklahoma State University

Two experiments were conducted to examine Hebb's test of the "picture theory" of visually imagining words. Experiment I examined retrieval from visual image representations of words by using a method of probing for the spatial properties of the *i*th letter in an imagined word. Evidence was obtained for a limited-capacity visual image system that can represent 3- and 5-letter words, in a spatially parallel manner, as efficiently as they can be represented in a visual percept system. Experiment II examined the generation of visual image representations of words. All parts of a word were not generated simultaneously, and generation generally did not proceed from left to right. The results of the 2 experiments were interpreted as indicating the existence of a visual image operating memory of limited letter capacity. The contents of the memory can be examined in much the same way as visual percepts.

Hebb (1966, 1968, 1972) and Woodworth and Schlosberg (1954) describe at length what we might term the "picture theory" of visual imagery. According to this theory, a self-generated mental picture or image can be examined in much the same way as a physical picture is examined by perception. For example, many people report visual images of whole lines or stanzas of verse, or at least of single words. The presumption is that these images are spatially parallel, i.e., all words or letters in the composite image are simultaneously available. Hebb proposes a test of the picture theory. The test contains a general requirement that there exist analogs between perception and imagery for the processing of spatial information, and a particular requirement that these analogs reveal themselves in a spelling test. To experimentally verify the picture theory, Hebb feels it is necessary to show that *S*s can spell imagined words in a backward direction as fast as they can in a forward direction. Since he finds that the backward spelling of imagined words is much slower than the forward spelling, Hebb (1966) concludes that whatever the nature of a visual memory image, it is not like having a mental picture which can be examined by the "mind's eye":

> the subjective impression that one can "look at" one's image freely is shown by objective test to be wrong [pp. 43–44]. The fact that the person with visual imagery can only "see" the letters of a word in left-to-right order shows clearly that the memory image . . . is a *series* of events in a *particular order*, not a picture whose parts could be looked at in any order (or simultaneously) [p. 46; italics added].

It is the contention of this article that, with qualifications, the picture theory of visual imagery is at least partly correct, and that Hebb's (1966) general requirement (that there exist analogs between percept and image processing) is a perfectly reasonable test of the theory. However, we feel that Hebb's particular requirement, a comparison of forward and backward spelling times, is not appropriate, for the following reasons. First, a spelling test is not necessarily visual. The *S* may simply draw on a highly practiced and extensively trained verbal/speech representation of the word when spelling it. Second, the spelling test may involve an assymetrical use of verbal and visual image representations. The *S* may indeed have a visual image representa-

tion of the word but may still use his familiar verbal/speech representation for spelling in a forward direction, while possibly dropping back to his visual representation for the unfamiliar backward spelling. The more rapid forward spelling would then simply follow from the fact that, for sequential items, speech is a more rapid process than visual imagery (Weber & Castleman, 1970). Third, the visual perception system may have a substantially greater spatially parallel processing capacity than the visual imagery system. A suggestion that the visual imagery system may be of very limited capacity has been put forth by Weber, Kelley, and Little (1972). If visual imagery is of more limited capacity than visual perception, a spelling test using long words, e.g., *university*, may be biased in favor of perceptual performance. Fourth, even if capacity limitations were equal for the image and percept systems, the way in which items (letters) sequenced in and out of the 2 systems might well differ (Weber et al., 1972).

In the present study, an attempt was made to eliminate some of the difficulties associated with Hebb's (1966) spelling test. First, to make more certain that *S*, when requested to visually imagine a word, does indeed use a visual representation, these experiments required *S* to respond to visual spatial properties of the letters in a word. In particular, we asked *S* to imagine words with lowercase printed letters and to classify a given letter for the spatial property of vertical height. Those letters that are vertically large (b, d, f, g, . . ., y) would fall in the *yes* category and all other letters would fall in the *no* category (Weber & Castleman, 1970; Weber & Kelley, 1972; Weber et al., 1972). This procedure allows for a set of converging factors which point to the conclusion that a visual image system rather than a verbal system is involved. The converging factors are: (*a*) the ability of *S*s to correctly classify the imagined letters for vertical height, (*b*) frequent subjective reports from *S*s that they do visualize during the task, and (*c*) the finding of highly distinctive rates of processing for visual image [illegible] speech instructional sets ([illegible] Castleman, 1970). Second, to [illegible] maximum parallel representation [illegible] ual image and to avoid building [illegible] essary sequential processing, a [illegible] ort probe technique was used [illegible] ent studies. In this technique, [illegible] osition in a word is indicated by [illegible] robe, with probe position define[illegible] to right. The letter correspo[illegible] probed position is then classifi[illegible] d height by *S*. The probe te[illegible] allows for a direct compari[illegible] ept and image representation [illegible] xamination of capacity effect [illegible] nulus words of different length [illegible] nted.

Experime[illegible] rd Probe

This experi[illegible] oncerned with comparing retri[illegible] om an available image vs. an ava[illegible] ept representation. The follo[illegible] ons were asked: Does response [illegible] for image and percept conditions vary as a function of the number of letters in a word? Do the functions relating RT to probe position differentiate between image and percept representation?

Method

Subjects. Sixteen experimentally naive volunteer *S*s with normal or corrected vision were tested individually. Each *S* was previously screened in a manner similar to that of Weber and Castleman (1970) for ability to respond to a visualized alphabet.

Stimuli and procedure. The test stimuli were nouns and adjectives with a Thorndike–Lorge (1944) count of 5 or more per 100,000 occurrences.[3] A total of 42 different words were used. Twelve were test words of 5 letters in length and 12 were test words of 3 letters in length. In addition, there were 8 filler words 3 letters in length (for statistical balancing purposes) and, finally 5 practice words for each word length. The 12 5-letter test words were selected such that vertically large lowercase letters (b, d, f, g, h, j, . . ., y) and vertically small letters (a, c, e, . . ., z) appeared equally in all 5 letter positions (first through fifth). The 12 3-letter test words and 8 3-letter filler words were also

[3] Strictly speaking, this was true only of the word stem. Occasionally, for example, a 4-letter word might have been used with a plural form (*s* added) in order to satisfy conditions and yield a satisfactory 5-letter word.

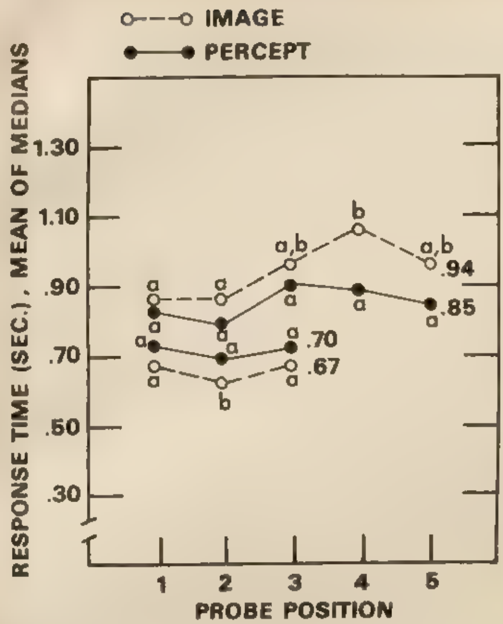

FIGURE 1. Response time as a function of image–percept representation and letter position probed in Experiment I.

selected so that vertically large and small letters appeared equally in all 3 letter positions.

Each S was given a preliminary spelling test for the words that were to be used. He was required to "spell" the words both with letters and with *yes* and *no* (indicating the vertical height of the letters). For example, the word *cat* would be spelled *c*, *a*, *t* and *no*, *no*, *yes*, respectively.

The stimulus words were presented as images or as percepts. For the image conditions, E spoke the word and S was instructed to form a visual image of it with his eyes closed. Imagining something visually was explained to be like "picturing it in the mind." For the percept condition, each word was rear projected with a Kodak Carousel projector equipped with a solenoid-operated shutter. Letters appeared in lowercase elite type on a 30.48 × 20.32 cm. rear-projection screen. The vertically small letters were .63 cm. high. Since vertically large letters were slightly irregular in height, the *j*, 1.27 cm. in projected height, was taken as the standard. The S viewed the letters from a distance of 53.34 cm.

Four seconds after presentation of a stimulus word, E orally presented a probe digit (1–5). The probe digit indicated a letter position in the word S was imagining or perceiving. In a word like *cat*, the digit *1* referred to the *c*, *2* referred to the *a*, and *3* referred to the *t*. The 5-letter words were probed in the same fashion. The spoken digit activated a Lafayette voice relay and started a Standard clock. The S then responded *yes* or *no* to indicate whether the letter denoted by the probe digit was vertically large or not. The S's response stopped the clock, and RT from onset of the probe to onset of the response was recorded. For the percept conditions, after S responded, the slide terminated and a blank adaptation field was displayed from another projector with a solenoid shutter. All Ss were instructed to respond as rapidly as possible, with 100% accuracy. Any words which resulted in error were repeated at the end of the run. Hence, all time scores were for correct choices only.

Design. There were 2 levels of word length (3-letter and 5-letter words) and 2 modes of representation (percept and image). Word length was a between-Ss variable and representation mode was within Ss, with half of the Ss proceeding in the order image–percept and the other half in the order percept–image. There were 60 trials within each of the between-Ss conditions (each test word appeared 5 times in the 5-letter treatment and 3 times in the 3-letter treatment). This allowed each letter position in each word to be tested once and only once; the additional 3-letter filler words made it possible to equate practice on 3- and 5-letter words. Probe position was also treated as a separate within-Ss variable for each word length. Two different random orders of words were used.

Results and Discussion

Each S's median RT for a given condition was computed, and the mean of the medians was then obtained for Figure 1. Thus, each point represents 96 events (12 Words × 8 Ss). Medians were used because of the substantial variability encountered. The number to the right of each function is the mean RT obtained by collapsing across probe positions.

Several statistical analyses were conducted, and RT was the dependent variable in each case. In the first analysis of variance, data were collapsed across probe positions. That is, each S's score was the mean of his separate median probe position RTs. The resulting 2-way classification of 2 word lengths (3 and 5 letters) by 2 representation modes (image and percept) was analyzed, with the first factor between Ss and the second within Ss: for word length, F (1, 14) = 5.20, $p < .05$; for representation mode, F (1, 14) = .48, $p > .05$; and for the Word Length × Representation interaction, F (1, 14) = 2.82, $p > .05$. Thus, RT significantly increases with word length, but images and percepts are not reliably different in the speed with which spatial information is extracted from them. Indeed, processing time from the

3-letter image condition is at least as fast as that from the 3-letter percept condition.

The second series of analyses examined probe position effects. Consider the 3-letter words. Here, the analysis was based on a 2-way classification of 3 probe positions (1, 2, and 3) by 2 representations (image and percept), with both factors within *S*s: for probe position, $F\ (2, 14) = 7.64$, $p < .05$; for representation mode, $F\ (1, 7) = .94$, $p > .05$; and for the Probe Position × Representation interaction, $F\ (2, 14) = .09$, $p > .05$. Thus, the dip in RT for the middle letter is significant, suggesting that all parts of a word are not processed equally rapidly.

To examine this serial position effect more closely, separate Newman–Keuls tests were performed for the 3-letter percept and 3-letter image conditions. The results are indicated by the letters adjacent to each plotted position in Figure 1. Within the range of each function, the probe positions having the same letter do not differ significantly; however, the probe positions having different letters *do* differ significantly ($p < .05$). Hence, the 3-letter percept condition may be regarded as statistically flat, a result consistent with a random access process. But the 3-letter image condition indicates a significantly faster processing time when the second-letter position is probed. However, it is appropriate to reemphasize that the Probe Position × Representation interaction was not significant in the analysis of variance for probe position effects.

In a comparable series of analyses for the 5-letter word conditions, the following results were obtained: for probe position, $F\ (4, 28) = 4.97$, $p < .05$; for representation mode, $F\ (1, 7) = 1.88$, $p > .05$; and for the Position × Representation interaction, $F\ (4, 28) = 2.28$, $.05 < p < .10$. Again, the probe position effect shows that not all parts of a word are processed at the same rate.

The Newman–Keuls test results are indicated in Figure 1 in the manner described previously. The 5-letter percept function is statistically flat, while there appears to be a serial position effect developing for the 5-letter image fun[illegible] However, it should be noted that [illegible] Probe Position × Representation M[illegible] interaction fell short of significanc[illegible] the analysis of variance for 5-letter [illegible] position effects. It is our impression [illegible]he data indicate that *S*s' capacities [illegible]isually imagine letters were strained [illegible] 5-letter image condition. This may [illegible] either that 5 letters cannot be eff[illegible] visualized all at once or that the st[illegible] [illegible] the image is decreased and all or [illegible] fades in and out. The *S*s may co[illegible] for this lost capacity in several w[illegible]ey may verbally mediate some [illegible] the letter images along the line[illegible]ed by Weber et al. (1972). They [illegible] some of the letters in a visual ima[illegible] not all of the letters of a word may [illegible]erated for use at the same time. The data are not sufficient to decide.

It is appropriate to note that preliminary analyses were also performed in which *yes/no* response categories were treated as a separate factor. No consistent effects distinguishable from the present results were apparent.

To summarize, there are differences in processing time between 3- and 5-letter word conditions. There do not seem to be significant differences in processing time for overall image vs. percept representation, but there may be differences in probe position effects. In regard to probe position effects, percept condition processing is consistent with random access to serial positions, but image condition processing may not be indicative of strict random access to serial positions.

Experiment II: Probe Word

Experiment I examined differences in the processing of information from *available* visual images vs. *available* visual percepts. The present experiment is concerned with examining differences in the processing of information from visual images vs. visual percepts, during the generation process. By presenting the probe before the word that is to be imagined or perceived, the necessity for generating an image or percept is added to the task. The temporal growth

of the image or percept can then be examined.

Method

Sixteen experimentally naive *S*s with normal vision were paid for their participation and were tested individually. All stimulus materials and procedures were identical to those of Experiment I except that the probe digit was presented first and then was followed by the stimulus word.

Results and Discussion

The treatment of the results, summarized in Figure 2, was identical to that of Experiment I. When the probe position variable was collapsed, the resulting 2-way analysis of word length by representation mode indicated significant effects of word length, $F\ (1,\ 14) = 7.69$, $p < .05$; representation mode, $F\ (1,\ 14) = 249.58$, $p < .05$; and the Word Length × Representation interaction, $F\ (1,\ 14) = 9.72$, $p < .05$. In Experiment I, only the word length variable was significant. The present results indicate that it takes significantly longer to generate and process an image than it does a percept. The significant Word Length × Representation interaction is indicative of some form of limited capacity in the visual image generating and processing system. As the word to be generated becomes longer and exceeds processing capacity, RT becomes disproportionally longer for the image conditions in comparison to the percept conditions.

Separate serial position analyses were performed for each word length. For 3-letter words, an analysis of probe position by representation mode yielded significant effects of position, $F\ (2,\ 14) = 14.56$, $p < .05$; representation, $F\ (1,\ 7) = 336.78$, $p < .05$; and no significant interaction, $F\ (2,\ 14) = 2.93$, $p > .05$. The Newman–Keuls test for 3-letter word conditions indicated that the percept function is statistically flat and that for the image function each probe position is statistically different from the other 2. Thus, generating percepts appears to be an all-at-once parallel process, and the generation appears to have no effect on the processing of information from the percept. The increasing 3-letter image function is consistent with a left-to-right generating and/or processing strategy.

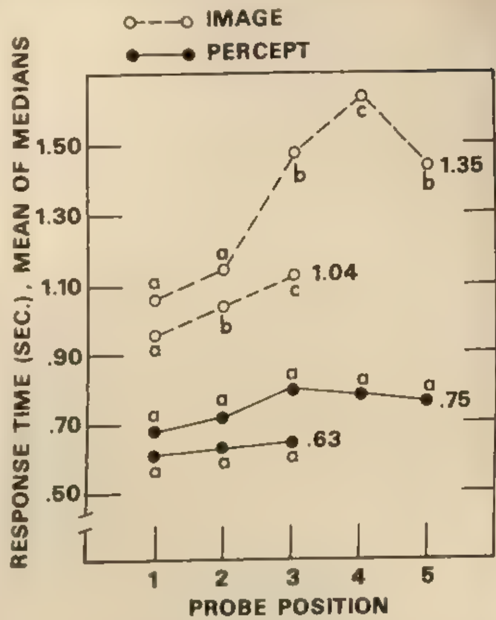

FIGURE 2. Response time as a function of image–percept representation and letter position probed in Experiment II.

The serial position analyses for 5-letter words indicated the following. In the probe position by representation analysis, the effects of position, $F\ (4,\ 28) = 26.76$, $p < .05$; representation $F\ (1,\ 7) = 99.06$, $p < .05$; and the Position × Representation interaction, $F\ (4, 28) = 13.77$, $p < .05$, were significant. The Newman–Keuls test indicated that the percept function is statistically flat and that the image function has an inverted-U form. These results are not consistent with a left-to-right generating and/or processing strategy.

In summary, percept functions remain statistically flat even when the probe is presented prior to the word. Generation processes of the type studied here seem minimal in perception, and there still appears to be random access to the different serial positions. The random-access process could occur in at least 2 different ways. First, the percept representation could be of a spatially parallel nature in which all the letters are simultaneously available for processing. Second, after receiving the probe digit, *S* could simply visually fixate

on the appropriate letter location on the viewing screen in anticipation of the forthcoming word. The latter process would not be very interesting theoretically. Moreover, it would not explain the flat percept functions of Experiment I, where the locus of the probe position was uncertain.

General Discussion

The picture theory of visual imagery was supported in Experiment I; Hebb's (1966) general requirement that performance analogues exist for percept and image representation was satisfied. Access to a 3-letter image representation was at least as rapid as to a 3-letter percept representation. Access to a 5-letter image representation was not significantly slower than to a 5-letter percept representation. However, there was some suggestion of an emerging Percept–Image Representation × Word Length interaction. This interaction was strongly present in Experiment II, which dealt with image generation time.

Our explanation for these findings is that there exists a visual image operating memory with a fixed letter capacity for parallel processing that is less than that of the visual percept system. When the image capacity of the operating memory is strained or exceeded, differences in processing time between percept and image systems become apparent. These differences reveal themselves in effects of word length and/or serial position. The effects were more apparent in Experiment II, where the image had to be both generated and scanned, than in Experiment I, where the image could have been generated and available some time before scanning began. As a partial independent check on this capacity interpretation, we have since performed several scaling studies of *S*s' subjective impressions of how many letters they can visualize at one time. The median number of alphabetic letters simultaneously visualizable was found to be 5, with an ascending method of limits procedure ($n = 31$), and 6, with a numerical estimate procedure ($n = 24$). These scaling values seem very supportive of the results from Experiments I and II.

If the visual image system does have a capacity limitation, it is of interest to know how this limitation is handled. Weber and Kelley (1972) and Weber et al. (1972) have found evidence that when an array of letters such as an alphabetic list or long word (e.g., "supercalifragilisticexpialidoccious") exceeds the spatially parallel capacity of the visual image system, a verbal sequencing comes into play. Briefly, what happens is that *S* says to himself each successive letter or syllable name prior to visually imagining it. This verbal sequencing allows for the sequential ordering and generation of visual images and is in sharp contrast to perceptual presentation, where *S* need only visually scan or move his eyes from one letter or syllable locus to another (Weber & Kelley, 1972) in order to sequence through a list. Thus, the capacity of the visual percept system is essentially unlimited as long as the time requirements are not so stringent as to limit visual scanning and/or eye movements. In this view, the mode of sequencing between letters or syllables seems to be one fundamental distinction between the visual image and visual percept systems.

In conclusion, the majority of the findings of the present study indicate that the picture theory of visual imagery may have much more to recommend it than has previously been supposed (Pylyshyn, 1973). This is not to say, however, that there are no differences between percept and image systems. One important difference seems to be in the manner of sequencing between items (letters) in a list that exceeds capacity. There are, no doubt, other differences to be discovered.

VERBAL DISCRIMINATION AS A CONCEPT-ATTAINMENT TASK USING THE EVALUATIVE DIMENSION [1]

MARIAN SCHWARTZ [2]

University of Wisconsin—Madison

In Experiment I, a verbal discrimination task was used in which correctness was determined by a relational rule based on the evaluative dimension. Each pair consisted of a neutral word paired with an extreme ("good" or "bad") word. When the word closer to the positive pole of the dimension was correct, performance was significantly better than when correctness was randomly determined. When the word closer to the negative pole was correct, performance was not significantly different from the random control. These results, coupled with the results of a postlearning questionnaire, suggest that most *S*s failed to conceptualize the evaluative dimension as a single bipolar continuum. In Experiment II, it proved harder to judge which member of a pair was closer to the negative end than to judge which was closer to the positive end of the dimension, indicating an asymmetry in rule utilization as well as in rule discovery.

Several recent experiments have found that the evaluative attributes of words can be a basis for concept attainment (Di Vesta & Ingersoll, 1969; Haygood, 1966; Rhine, 1965; Rhine, Cole & Ogilvie, 1968; Taylor & Haygood, 1968) or for differential encoding in memory, as indexed by release from proactive inhibition (Wickens & Clark, 1968). These studies used stimulus words drawn from the positive (good) and negative (bad) halves of the evaluative dimension of connotative meaning. The results have been interpreted (e.g., Haygood, 1966; Wickens & Clark, 1968) as evidence that positive and negative words constitute psychologically distinct classes, and as providing at least partial validation for the evaluative scale of the semantic differential.

According to the bipolar model which underlies the semantic differential (e.g., Osgood, Suci, & Tannenbaum, 1957), each scale is assumed to represent a single bipolar dimension extending as a straight line in semantic space, with the midpoint of the line passing through the origin of this space. As applied to the evaluative dimension, such a model implies not only that positive and negative words should constitute different psychological classes, but that these two classes of words should be perceived (responded to) as belonging to the same dimension; and further, that evaluatively neutral words should be perceived as falling along this same dimension midway between the two extremes.

The present study tested some of the implications of the bipolar model, as it applies to the evaluative dimension, by investigating the attainment of concepts based on relational rules. In Experiment I, a verbal discrimination (VD) paradigm was used to present pairs of words in which one member was evaluatively neutral and the other was either positive or negative. Correctness was determined by one of two rules. Under the positive rule, the correct member of each pair was the one closer to the positive pole of the dimension; under the negative rule, the correct member was the one closer to the negative pole. It was expected that *S* should discover and utilize the appropriate relational rule if, in accordance with the bipolar model, *S* conceptualized positive, neutral, and negative words as being monotonically ordered along the same dimension. More specifically, if the bipolar model is applicable to performance in the

[1] This research was supported in part by a National Institutes of Health Biomedical Sciences Support Grant to the Graduate School of the University of Wisconsin. Experiment I was reported at the Psychonomic Society meeting, St. Louis, November 1971.

present task, the following outcomes would be expected: (*a*) Where correctness is determined by a relational rule, VD performance should be significantly above the level of a control group in which correctness is randomly determined. (*b*) The positive and negative rules should be equally effective. (*c*) Assuming that *S*s are able to verbalize the rules when questioned at the end of learning, they should tend to express the rules in relational rather than absolute terms. For example, the positive rule could be expressed either as a relative statement such as, "The more positive (closer to good) member of each pair was correct" or in absolute terms, such as, "Where a neutral and a good word were paired, the good word was correct; where a neutral and a bad word were paired, the neutral word was correct." The relational form, but not the absolute form, reflects the idea of a single bipolar dimension ranging from good through neutral to bad.

A secondary question concerned the effect of instructions upon discovery of the appropriate rule. Some *S*s were given an instructional clue to the effect that correctness was rule-determined and that the rule involved evaluative attributes. The presence or absence of this instructional clue was orthogonal to type of rule.

Experiment I

Method

Design. There were five independent groups: positive, instructed-positive, negative, instructed-negative, and random. The positive rule applied to the first two groups; the negative rule, to the next two groups. Both instructed groups received the same instructional clue, and this clue constituted the only difference in treatment between the two instructed groups and their uninstructed counterparts. In the random (control) group, correctness was randomly determined. The random group, therefore, could learn the list only by rote; the four rule-determined groups could learn either by rote, or by making use of an appropriate rule, or by some combination of rule and rote.

Lists. All groups learned a list of 16 pairs in which 8 pairs were neutral-good (i.e., a word rated neutral paired with a word rated good) and 8 were neutral-bad. The construction of the lists might be called semi-double-function. That is, each neutral word occurred in two pairs in the same list (e.g., the pairs AMOUNT, HOPE, and AMOUNT, CRIME), being correct in one pair and incorrect in the other. Subjects cannot master such a list by learning which individual words are correct; they must take the other member of the pair into account. The list was constructed in this way to increase the difficulty of rote learning and to encourage attention to both members of each pair, thereby maximizing *S*'s opportunities to discover the appropriate relational rule.

The occurrence of each neutral word in two pairs while each extreme (good or bad) word occurred in only one pair should introduce a bias in favor of the neutral words, according to the frequency theory of VD learning (Ekstrand, Wallace, & Underwood, 1966). That is, all other things being equal, the accumulation of more frequency units for the neutral words should produce more correct responses for pairs in which neutral words are correct than for pairs in which neutral words are incorrect. A bias favoring neutral words, however, should not differentially affect performance as a function of group, as in all five groups the neutral member was the correct one for half of the pairs.

In selecting the words to be used, it was desired to equate the good, bad, and neutral sets on irrelevant variables, but this was not feasible using published lists of words rated on the evaluative dimension. Accordingly, a set of 224 nouns which appeared by inspection to be unequivocal in their goodness, badness, or neutrality were drawn from the Paivio, Yuille, and Madigan (1968) norms. As a check on *E*'s judgments, these nouns were then rated on a 5-point evaluation scale by 16 students recruited from a course in introductory psychology. Three sets of nouns—8 good, 8 bad, and 8 neutral—were then chosen to meet the following criteria: (*a*) the three sets were equated as far as possible in word length, in number of first-letter duplications, and in the variables of frequency, imagery, and meaningfulness as measured by the scales provided in the Paivio et al. norms, and (*b*) the designation of words as good, bad, or neutral on the basis of *S* ratings should be as unequivocal as possible. The 128 ratings made by the 16 raters for the 8 words in each set break down as follows: for the good set, 97% of the ratings were either Very Good or Somewhat Good, and 3% were Neutral; for the bad set, 97% were either Very Bad or Somewhat Bad, and 3% were Neutral; for the neutral set, 88% of the ratings were Neutral, 6% Somewhat Good, and 6% Somewhat Bad. It is recognized that, because of the rough scaling procedure and small number of scalers, the sample of neutral words selected may not adequately represent the psychological midpoint between the samples of good and bad words selected. If an imbalance of this kind exists, however, it should not bias the comparison between groups, since the same pairs were used for all groups. (This point is covered more fully in the discussion of the results.) The words selected for the good set were FREEDOM, GIFT, HOPE, HUMOR, KINDNESS, MOTHER, TRUCE, VIGOR; for the bad set, ASSAULT, CRIME, DEATH, DECEIT, PYTHON, SLAVE, TROUBLE, VICTIM; and for the neutral set, AMOUNT, ANKLE, FORK, HAIRPIN, INSTANCE, LENGTH, PRODUCT, UNIT.

Eight 16-pair lists were constructed. In each list, the 8 neutral words each occurred in two pairs and the remaining 16 words each occurred in one pair. The eight lists comprised two basic pairings with four versions of each pairing. The four versions differed only with respect to the designations of the correct pair members. In one version, the positive rule applied; i.e., the correct words were the positive members of neutral–good pairs and the neutral members of neutral–bad pairs. In another version, the negative rule applied. Whichever member was correct in the positive version was necessarily incorrect in the negative. There were two random versions of each pairing, which differed in that whichever word was correct in one version was incorrect in the other. In each random version, the neutral members were designated as correct for half the neutral–good pairs and for half the neutral–bad pairs. Within each list, the number of pairs with the shorter word correct equaled the number with the longer word correct.

Four orders of presentation were used for each list. The orders were random subject to certain restrictions, such as that no more than three consecutive pairs could be of the same type (i.e., neutral–good or neutral–bad). The assignment of the correct member to the upper or lower position within a pair was random subject to certain restrictions designed to prevent confounding between intrapair position and any other variable.

A practice VD list of eight pairs of numbers was constructed by pairing the numbers 1–16, with each number occurring in one pair. In the practice list, pairing and correctness were random subject to certain restrictions designed to minimize the possibility that any rule could be used as a cue to correctness. A single pairing, with four orders of presentation, was used for the practice list.

Procedure. Subjects were run individually. The practice list of numbers was presented until *S* reached the criterion of two perfect trials, not necessarily consecutive. The word list was then presented for 12 trials. All lists were shown by the anticipation method on a Stowe memory drum at a 2:2 rate, with an 8-sec. intertrial interval. The same starting order was used for all *S*s. Since the standard VD instructions to call out the correct member of each pair might induce a set toward evaluatively positive words, the instructions to *S* avoided the terms *correct* and *incorrect* (or *right* and *wrong*) in referring to the two members. Instead, instructions for both the practice list and the word list indicated that pairs would appear on the left-hand side of the memory-drum window, and that the task was to anticipate which member of each pair would appear on the right-hand side. The word-list instructions also informed *S* that some words would occur in more than one pair, and that a word which appeared on the right-hand side when it was a member of one pair would not necessarily appear on the right when it was a member of another pair. The only reference to rules or to the evaluative dimension occurred in the following sentence, which was added to the word-list instructions for the instructed-positive and instructed–negative groups: "There is a rule you can discover which will help you learn which words will appear on the right. I cannot tell you the exact rule, but it has to do with the extent to which words arouse reactions of goodness or badness." (The order of the words "goodness" and "badness" in this sentence was reversed for half the *S*s within each of these two groups.)

At the conclusion of the word list, an untimed written questionnaire was administered. The questionnaire instructions informed *S* that different people received different word lists, and asked him to check whichever one of the following three statements seemed to apply to his list: 1. It seemed to be arbitrarily determined which words would appear on the right. 2. There seemed to be a rule or principle determining which words would appear on the right. 3. For some word pairs, it seemed to be arbitrary; for other word pairs, there seemed to be a rule or principle. If *S* checked Statement 2 or 3, he was asked to write the rule.

Subjects. The *S*s were 40 paid summer session students, 20 men and 20 women, none of whom had participated in the original rating of the words to be used. Eight *S*s, 4 men and 4 women, were assigned to each of the five conditions, using a block randomization procedure. The two pairings of the word list were balanced over condition and sex of *S*, and the two versions of each random list were balanced over sex of *S*. Three additional *S*s were eliminated; 2 failed to reach criterion on the practice list within 18 trials, and the other had four failures to respond on the word list.

Results and Discussion

Practice list. Because all *S*s were treated alike on the practice list, performance on that list should not differ among the five groups. Mean trials to criterion ranged from 6.62 to 10.75 for the five groups, and analysis of variance confirmed that these practice-list differences were not significant ($p > .10$). Nonsignificant effects ($p > .10$) were also found for sex of *S* and for the Group × Sex of *S* interaction.

Word lists. Mean correct responses for the 12 word-list trials combined are shown in Table 1, and trial-by-trial data are shown in Figure 1, Panel A. An overall 5 × 2 × 2 analysis of variance was performed on the total number of correct responses. The independent variables were rule (positive, instructed–positive, negative, instructed–negative, and random), sex of *S*, and type of pair (neutral–good vs. neutral–bad). The variable of rule proved to be highly significant, F (4, 30) = 10.14, $p < .001$. Type of pair was also significant, F (1, 30)

TABLE 1

Mean Correct Responses on Word List, by Condition and Type of Pair

Condition	Type of pair: All pairs	Neutral–good	Neutral–bad
Random	148.50	73.50	75.00
Neutral word correct	76.62	37.88	38.75
Extreme word correct	71.88	35.62	36.25
Negative	156.62	81.25	75.38
Instructed–Negative	164.75	84.88	79.88
Positive	177.12	88.75	88.38
Instructed–Positive	189.75	95.25	94.50
All conditions combined	167.35	84.72	82.62

$= 4.95$, $p < .05$, with performance on neutral–good pairs somewhat higher than on neutral–bad. The only other factor approaching significance was the Rule × Type of Pair interaction, $F\ (4,\ 30) = 2.27$, $.05 < p < .10$.

As shown in Table 1 and in Figure 1, Panel A, the five rule groups in order from lowest to highest performance on the word list were random, negative, instructed–negative, positive, and instructed–positive. Dunnett's test was used to compare each of the four rule-determined groups with the random control. With $k = 5$ and $df = 35$, performance was significantly above the random-group level in the positive group, $t = 3.84$, $p < .01$, and in the instructed–positive group, $t = 5.54$, $p < .01$, but not in the negative, $t = 1.09$, $p > .05$, or instructed–negative, $t = 2.18$, $p > .05$.

An additional analysis comparing positive vs. instructed–positive groups revealed a highly significant effect of instructions, $F\ (1,\ 14) = 22.75$, $p < .001$. The analogous negative vs. instructed–negative comparison did not approach significance ($F < 1$).

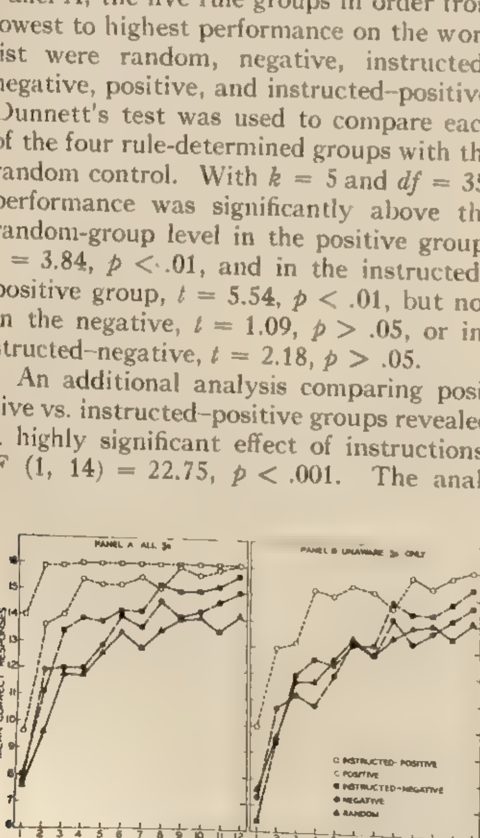

Figure 1. Mean correct responses on word list, by condition.

The major results for the rule variable may be summarized as follows: Where the positive rule governed correctness, performance was significantly better than in the random group, where learning could occur only by rote; where the negative rule governed correctness, performance was slightly but not significantly above the random-group level. These results held both for the instructed and for the uninstructed groups.

The question might be raised whether the superiority of the positive to the negative rule could be accounted for in terms of a simple response bias; i.e., a general tendency to choose positive and or avoid negative words (cf. Boucher & Osgood, 1969). Against this interpretation is the finding that, within the random group, correct responses averaged almost the same for those pairs with the "closer to negative" word correct (74.13) as for those with the "closer to positive" word correct (74.37). Further, supplementary analyses were conducted in order to rule out the possibility that such a response bias may have contributed to the comparisons between the random and rule-determined conditions. The random-group lists were divided into two subsets—those eight pairs in which the "closer to positive" word was correct, and those eight pairs in which the "closer to negative" word was correct—and the number of correct responses in each subset was multiplied by two. Then separate analyses of variance were used to compare each of the four rule-determined conditions with the appropriate subset of random-group pairs; e.g., the positive group was compared with the "closer to positive" set. The results of these analyses mirrored the results of Dunnett's test reported above.

It might also be pointed out that the obtained asymmetry between the positive and negative rules could not be accounted for by a failure of the three sets of words to mark off two psychologically equal intervals along the evaluative dimension. That is, assume that, either because of deficiencies

in the sample of words selected or because of some peculiarity of the evaluative dimension per se, it was harder to differentiate between neutral and negative words than between neutral and positive words. This should make it harder to apply both rules to the neutral–bad than to the neutral-good pairs. It should not make it harder to apply the negative rule than to apply the positive rule, however, since the specific pairs and, hence, the specific intrapair intervals would necessarily be the same regardless of rule.

It appears, therefore, that the negative rule was harder to discover and/or harder to utilize than the positive rule, and that this outcome was neither an artifact of unequal intervals nor the consequence of a general bias toward positive and against negative words.

Turning to the type of pair effect, performance for the five groups combined was significantly better on the neutral–good pairs than on the neutral–bad. Although the Rule × Type of Pair interaction failed to reach conventional significance levels ($.05 < p < .10$), Table 1 shows that the type of pair effect was not manifest in all groups, but was concentrated in the negative and instructed–negative conditions. This marginal interaction suggests that the superiority of the neutral–good pairs should not be interpreted simply in terms of psychologically unequal intrapair intervals. Rather, the finding of better performance on neutral–good than on neutral–bad pairs in the two negative-rule conditions is consistent with a frequency bias, since frequency would favor pairs with the neutral word correct, and under the negative rule those would be the neutral–good pairs. Further evidence for a frequency bias is found in the random group. There, frequency would not affect the comparison between neutral–good and neutral–bad pairs, but would favor those pairs with the neutral word correct as opposed to those with the extreme word correct. The figures in Table 1 (76.62 vs. 71.88) are consistent with this expectation. In the positive and instructed–positive groups, however, any frequency bias would work to the advantage of the neutral–bad pairs, and there is no evidence of such a bias. It may be speculated that the tendency to choose the more frequently occurring word played a substantial role in those conditions where learning was entirely or mainly by rote, but not in those conditions where learning was largely by rule.

TABLE 2

MEAN CORRECT RESPONSES ON WORD LIST, BY RULE CONDITION AND AWARENESS CATEGORY OF *S*

Rule condition	"Unaware" *S*s: *N*	"Unaware" *S*s: Correct responses *M*	"Unaware" *S*s: Correct responses Range	"Aware" *S*s: *N*	"Aware" *S*s: Correct responses *M*	"Aware" *S*s: Correct responses Range
Negative	6	148.33	122–172	2	181.50	176–187
Instructed–Negative	5	152.80	133–169	3	184.67	180–189
Positive	5	174.60	163–184	3	181.33	175–186
Instructed–Positive	0	—		8	189.75	188–192

Questionnaire. The 32 *S*s in the four rule-determined conditions were labeled "Aware" or "Unaware" on the basis of their responses on the postlearning questionnaire. A total of 16 *S*s checked Statement 2 indicating that a rule seemed to apply. All these *S*s then wrote rules which, while variously phrased, may be considered correct or closely correlated with the correct rule. These 16 *S*s were labeled "Aware." The 9 *S*s who checked Statement 1 to indicate that no rule seemed to apply were labeled "Unaware." The remaining 7 *S*s checked Statement 3 to indicate that a rule seemed to apply to some but not all pairs. Since none of them wrote a rule which could be considered correct or partly correct, these 7 *S*s were also labeled "Unaware." (There was essentially no difference in learning between these two subgroups within the Unaware category.)

Table 2 shows the number of *S*s labeled Unaware and Aware according to the criteria specified above. Also shown is the number of correct responses (out of a maximum possible of 192) for these two classes. All *S*s in the instructed–positive condition fell in the Aware category and, in view of their near-perfect performance, they probably discovered the positive rule on the first

trial. In the other three rule-determined conditions, only a minority of *S*s had discovered the correct rule by the end of the 12 learning trials. The range columns indicate that, within the two negative-rule groups, there was no performance overlap between Aware and Unaware *S*s. Within the positive condition, VD performance was not so strongly related to verbalization of the rule.

In view of the relatively high level attained by the five positive-condition *S*s classified as Unaware (see Table 2 and Figure 1, Panel B), their performance was compared with that of the eight *S*s in the random condition, and the difference was found to be significant, $F\ (1, 11) = 13.18$, $p < .01$. It thus appears that awareness of the positive rule—defined in terms of verbalization of the rule on the questionnaire—was not a necessary condition for its effective operation. (It might be noted that the mean correct of 174.60 among the five *S*s in question reflected equally the performance of three *S*s who checked Statement 1 and two *S*s who checked Statement 3; mean correct responses in those two subgroups averaged 174.33 and 175.00, respectively.)

A surprising finding was that the instructional clue, which had a marked effect both on the questionnaire results and on VD performance under the positive rule, had virtually no effect under the negative rule. A reasonable supposition is that an instructional clue which calls attention to evaluative attributes but does not furnish a specific rule has the effect of predisposing *S*s to try the positive rule, or an approximation of it, as their first hypothesis. In the instructed–positive group, this led to immediate discovery of the correct rule and near-perfect VD performance. In the instructed–negative group, when this first hypothesis proved wrong, most *S*s apparently reverted to rote learning and, accordingly, performed at the random-group level.

In considering the applicability of the bipolar model to performance in the present task, the form in which *S*s verbalized the rules is highly relevant. Of the 16 Aware *S*s (i.e., those *S*s who stated some version of the correct rule), only 6 stated a relational rule applicable to both types of pairs (e.g., "The more positive of the two words appeared" or "Pick the less appealing word of the pair"). The remaining 10 *S*s used absolute rather than relative terms to state, in effect, a separate rule for each type of pair (e.g., "A word associated with positive emotions appeared on the right; in pairs with negative emotions, the neutral word appeared," or "Anytime one of the words in the pairs had a positive value associated with it, the neutral word is shown on the right. A negative value appears on the right"). Assuming that *S*'s statement of the rule on the questionnaire corresponded to his formulation of it during learning, it appears that most *S*s who discovered a workable rule did not utilize the idea of an underlying good–neutral–bad continuum, since they failed to conceptualize the choice of a neutral word in some pairs and an extreme word in other pairs as following from the same relational rule. (If the relevant dimension were size instead of evaluation, an analogous outcome would be for most *S*s to formulate a rule such as, "When small is paired with medium, pick small; when large is paired with medium, pick medium" instead of the simpler relational rule "Pick the smaller one.")

Experiment II

A distinction can be made between the discovery of a rule and its utilization. The learning data combined with the questionnaire results of Experiment I indicated that the negative rule was harder to discover than the positive rule. Experiment I left indeterminate the question of whether the negative rule may also be harder to utilize than the positive rule. The purpose of Experiment II was to make a simple and direct test of the relative difficulty of applying these two rules. The task was one of judgment rather than learning.

Method

A positive group and a negative group received the same treatment except for instructions. The 16 pairs from Experiment I were presented on a memory drum at a 2-sec. rate, without feedback.

The positive group received the following instructions: "Decide which word would seem more good, or at least less bad, to most people, and call out that word. That is, of the two words, call out the one most people would say is closer to being good." The negative group received the same instructions except that the words "good" and "bad" were interchanged. (A normative rather than an idiosyncratic judgment was requested for consistency with Experiment I; i.e., in Experiment I, those *Ss* who discovered a rule would presumably have applied it on the assumption that the rule had a normative basis.) Both pairings from Experiment I were used. Within each pairing, there were two versions which were reversed with respect to intrapair top-bottom position. Lists were balanced over groups. The *Ss* were run individually. Each *S* received four trials, with a switch from one rule to the other after Trial 2. Data are reported for Trial 1 only, however, in view of the small number of errors made on Trials 2–4 and the difficulty of evaluating transfer effects.

The *Ss* were 32 paid summer session students, 16 men and 16 women, none of whom had participated in Experiment I or in the original rating of the words to be used. Sixteen *Ss*, 8 men and 8 women, were assigned to each of the two groups, using a block randomization procedure. Five additional *Ss* were eliminated, 3 because of *E* errors, 1 because he refused to judge several pairs, and 1 because he consistently selected all neutral words as "closer to good" and all extreme words as "closer to bad."

Results and Discussion

Results are reported in terms of mean errors, an error being either a response which is the normatively "wrong" member of its pair, or a failure to respond. The number of errors made on the 16 pairs ranged from 0 to 3 in the positive group, with a mean of .94, and from 0 to 7 in the negative group, with a mean of 2.19. On the neutral–good and neutral-bad pairs, respectively, mean errors were .75 and .19 in the positive group, 1.44 and .75 in the negative group. Because of apparent skewness and heterogeneity of variance, the analysis was performed on a Freeman–Tukey square root transformation of the error data (Mosteller & Bush, 1954). A $2 \times 2 \times 2$ analysis of variance with rule, sex, and type of pair as the three variables yielded significant effects for rule, $F(1, 28) = 5.01$, $p < .05$, and for type of pair, $F(1, 28) = 8.08$, $p < .01$. No other main effects or interactions were significant.

Considering first the main effect of type of pair, performance on the neutral–good pairs was significantly worse than on the neutral–bad. This was in the opposite direction from the type of pair effect found in Experiment I. The different outcomes with respect to this variable reflect different tasks; i.e., Experiment I involved a mixture of rote VD learning, rule discovery, and rule utilization, while Experiment II involved only rule utilization. The Experiment I outcome may be attributable mainly to a frequency bias affecting those pairs learned by rote. The Experiment II result could be interpreted to mean that the psychological distance between the neutral and positive words was less than that between the neutral and negative words, but it is indeterminate whether this finding can be generalized beyond the specific pairs used. As indicated earlier, any deficiencies in the samples of words selected to represent the good, neutral, and bad sets would not bias the comparison between the positive and negative rules, but might produce a significant type of pair effect.

The critical outcome of Experiment II was the rule effect. The negative rule proved to be harder to apply than the positive rule. That is, for the same pairs presented in the same way, it was significantly harder to judge which member of the pair was closer to the negative end of the evaluative dimension than to judge which member was closer to the positive end. This result held equally for neutral-good and for neutral–bad pairs; the Rule × Type of Pair interaction yielded $F < 1$.

The combined results of Experiments I and II, therefore, indicate that the negative rule is both harder to discover and harder to apply than is the positive rule.

The superiority of the positive rule in the present study bears at least a superficial resemblance to an outcome which has been found consistently with certain reasoning problems involving evaluative comparisons. That is, linear syllogisms (three-term series problems) of the form, "A is better than B, B is better than C, which is best?" are solved more readily than logically equivalent problems of the form, "C is worse than B, B is worse than A, which is worst?" (e.g., Clark, 1969; De Soto, Lon-

don, & Handel, 1965). It is possible that there is a basic asymmetry, one of wide generality, in the ability to use relational rules based on evaluative attributes. It cannot be assumed, however, that the same cognitive operations underlie performance in these different tasks.

This study examined reaction times to probes of active memory and inactive memory. Matches were based on either physical identity (e.g., the letters AA) or associational identity (e.g., the letters Aa). The results showed that inactive memory probes were processed more slowly than probes of active memory, and that physical matches were faster than associational matches only in active memory. These results were interpreted in terms of the nature of the stored representation and its retrieval. It was concluded that differences between active and inactive memory searches were due to differences in the storage location, not the nature of the stored representation.

Verbal materials have been used to study memory since Ebbinghaus' (1954) pioneer experimental work in this area in 1885. One hundred years of this type of research has promoted the notion that memory in verbal form is of much greater relative importance than other nonverbal forms (graphic, tactile, etc.). Many theories of information storage and retrieval (e.g., Atkinson & Shiffrin, 1968) have been based entirely on the registration, transfer, and storage of linguistic or verbal information.

There are, however, indications that not all storage is verbal. In an attempt to examine coding processes, Posner and Keele (1967) presented to their *S*s 2 letters which, when viewed sequentially, were judged as *same* or *different*. These judgments were based on physical identity, which occurred when 2 letters (AA) were identical physically, or associational identity, which occurred when 2 letters had only the same name (Aa). They have shown that physical *same* matches are faster than associational *same* matches. The difference (name reaction time [RT] − physical RT = 80 msec.) was interpreted as a difference in processing time for different "nodes" or levels. The assumption was made that a physical identity match is based on a comparison of codes representing only the visual information, while associational matches are based only on a comparison of verbal labels or names.

Posner and Mitchell (1967) gave 2 possible explanations for the associational–physical match time difference. First, physical matches could be made prior to associational matches, or second, both comparisons could occur simultaneously, with the associational match taking longer to complete. An alternative explanation is that in the associational match condition (Aa) one item is recoded into the format of the other, and physical matches are then made. Swanson, Johnsen, and Briggs (1972) supported the hypothesis that the memory item(s) is recoded, not the final item (probe).

In short, it seems that with the comparison of 2 successive stimuli, the identity judgments are facilitated when physical identity exists. Such facilitation lasts for at least 1.5 sec. and probably as long as 6–9 sec. or longer (Phillips & Baddeley, 1971). So, it appears that visual information is used primarily in active or short-term memory, and such memory is not entirely verbal.

A distinction that is frequently made

[1] This study was sponsored in part by the National Science Foundation through Grant GN-534.1 from the Office of Scientific Information Service to the Computer and Information Science Research Center, Ohio State University. It was based on a dissertation presented in partial fulfillment of the requirements for the PhD degree to Ohio State University. Special thanks are due to George E. Briggs who served as the author's advisor and chairman of his dissertation reading committee, and to the reviewer for his valuable comments and suggestions.

involving storage of information is that between short- and long-term stores or active vs. inactive memory. Waugh and Norman (1965) were among the first to make such a distinction and provide empirical support. Their conclusion that the 2 systems were independent was based on differential effects of number of intervening items. Subsequent research has supported this distinction in terms of serial position recall differences (Glanzer & Cunitz, 1966; Loftus & Wickens, 1970) as well as physiological evidence (Milner, 1970). Baddeley (1966) suggested that semantic variables were most important in inactive memory, while phonemic ones were important in active memory. Shulman (1970, 1971) showed that this may be due to temporal and strategical factors, and that both variables can be effective in both systems.

Several recent studies are relevant to the question of information processing in active and inactive memory. Forrin and Morin (1969) combined the Sternberg (1966) fixed- and varied-set procedures (active and inactive memory) by presenting A, AB, or ABC (memory load [M] = 1, 2, or 3) to be retained across a block of trials (fixed set). This set is presumably held in inactive memory. Each trial, then, consisted of presentation of a varied set (M = 1, 2, or 3), followed by a probe of either active or inactive memory, or neither. This classification task is assumed to load both memory systems at the same time. They found that the RT – memory-load function for active memory probes was steeper (slower processing) than that of the inactive memory probes. However, the inactive set in Forrin and Morin's study was both highly familiar and practiced (relative to the different active sets) as well as overlapping in the formation of the memory groups. This overlap also could conceivably reduce the slope constant.

Sternberg, Kroll, and Nasto (1969) compared performance on active set (only) with performance on inactive set (only). There was less difference in practice of inactive and active probes than in Forrin and Morin's (1969) study and, because the same items (digits) were used in both tasks, there was no differential familiarity. Sternberg et al. found that the processing rate for the inactive memory probe was slower than for the active memory probes. A greater intercept for the inactive memory probes was interpreted as the time required to find the proper ensemble in inactive memory, while the increase in slope constant reflected a serial retrieval process of the inactive items into an active memory for comparison.

The present study questions this explanation of the slope difference and proposes an alternative explanation in terms of the nature of the coding used in binary classification tasks as a function of the presumed location of the stored memory set—i.e., active or inactive memory. It is predicted that visual or representational codes will be used in what is presumably active memory when verbal associates are not required for appropriate responding, while coding in what is presumably inactive memory will be based on the verbal labels even when these labels are not strictly required. These representational differences, then, might explain the processing rate differences between active and inactive memory probes. It is important to note that the distinction between active and inactive memory in this research is an operational one. A theoretical distinction, however, may find support in the results.

METHOD

To carefully examine the question of representational differences in different memory systems, acoustic similarity was manipulated in such a manner as to affect RT as a function of the presumed type of match. It was felt that acoustic similarity should alter the RT-memory-load functions only when the stimulus letters are in fact stored as associates, and these associational representations are used as the basis of comparison. That is, when physical representations are compared, acoustic similarity is not expected to be a potent factor in the comparison process.

Design. A repeated measures design was used in which 48 conditions were defined by the factorial combination of the following variables: memory load (1, 2, or 4 letters), memory system (active or inactive), type of match (physical or associational), acoustic similarity (similar or dissimilar), and type of response (match or no match). During each session 2 blocks of 84 trials were given and

the first 4 trials were excluded from analysis. Twenty of the remaining trials involved a no match of the probe and memory items and required a negative response. Of the remaining 60 trials, there were 15 trials each of the following types of match: (*a*) physical match of probe with active set, (*b*) physical match of probe with inactive set, (*c*) associational match of probe with active set, and (*d*) associational match of probe with inactive set.

The presentation of each type of material was randomized to minimize guessing. One level of memory load for the inactive set was used each session and the levels were counterbalanced so that across *S*s each level was used equally often in each ordinal position (first, second, or third) across 3 consecutive days. The inactive memory load was constant within each session to minimize confusion as to the contents of this set. All 3 levels of memory load for the active sets were used equally often in each block (10 trials/block). Given that restriction, the order of occurrence of the active memory load levels was randomized. Half of the *S*s had memory sets and probes drawn from an acoustically similar list for the first experimental sessions and a dissimilar list for the final 3 sessions. For the remaining *S*s the order was reversed.

Stimulus material. Nineteen letters of the alphabet were selected as stimuli and divided into 2 (overlapping) sets of 12 from which both memory items and probes were drawn. One set was composed of the following 12 acoustically similar letters: B, C, D, E, F, G, P, S, T, V, X, and Z. The second set was an acoustically dissimilar list comprised of the following 12 letters: A, C, D, H, K, M, Q, S, U, X, Y, and Z. Indices of acoustic confusion (Cónrad, 1964) were calculated separately for each set of letters, revealing much less acoustic similarity for the acoustically dissimilar list than for the acoustically similar list. The indices of visual confusion within each list (Townsend, 1970) were nearly identical.

The presentation of the memory sets was visual and simultaneous. For $M = 1$, the letter was in the upper left corner of a 2×2 cell matrix. The remaining cells were unfilled. For $M = 2$, the upper 2 cells contained the letters, and all 4 cells contained letters for the $M = 4$ condition. Both upper- and lowercase could be represented in one memory set. The occurrence was randomized; but, across a block of trials, both cases were represented equally often in the active memory sets.

The probe letters that could be in either case appeared in the center of *S*'s viewing screen and were selected from the same subset as the memory items. The probes were selected such that across the final 80 trials in each block there were 60 match and 20 no-match trials with an equal number of (*a*) upper- and lowercase probes (40 each), (*b*) associational matches and physical matches (30 each), (*c*) match with active set item and match with inactive set item (30 each), and (*d*) active set match probes of $M = 1$, 2, and 4 (10 each).

Procedure. In the initial session, instructions were given and *S*s had 1 block of 84 trials. All 3 levels of memory load were used for the active sets, but only $M = 4$ was used for the inactive set. The purpose of this was to develop a tendency for *S*s not to group or combine the memory sets into one set which is then rehearsed as a unitary active set. This, of course, is most difficult to do when the largest sets are used.

At the end of each session, *S* was shown his inactive set for the next session and asked to memorize it. At the beginning of the next session, *S* was asked to record his memory set to assure its storage in inactive memory. If the set or any part could not be recalled, he was again shown the entire set and given 5 min. to memorize it. Then, at the beginning of each block of trials, this set was displayed again and the regular sequence began. Following the inactive set, an active set was displayed for 3 sec. followed by a 1-sec. interstimulus interval. The probe item was then displayed and terminated after 2 sec. The time from the onset of the probe item to the initiation of *S*'s response was recorded as the primary dependent variable. The response was made by pressing a microswitch with the left or right index finger. For half of the *S*s, the left finger indicated a match while the right indicated no match. The reverse was true for the other *S*s. Following the probe there was a 3-sec. intertrial interval prior to the presentation of the next active set. Thus, the total duration of one trial was 10 sec. This sequence was repeated until the end of the block of trials. After a brief rest, the inactive set was again displayed, and the sequence was repeated with different active memory sets.

Subjects. The 24 right-handed *S*s were volunteers responding to an ad in the campus newspaper. Each was paid \$1.25 for each session. There was 1 practice session, 6 experimental sessions, and 1 debriefing session on 8 successive work days.

Apparatus. The *S* sat in a dimly lighted, sound-damped room before a response panel and a ground-glass screen. On the response panel, which was at tabletop level, were 2 buttons marked "match" and "no-match." The marking, of course, corresponded to the particular finger assignment of each *S*. The stimulus materials were rear projected at eye level on the screen and measured 20×20 mm. for the 2×2 array. Each letter was approximately 10 mm. high and was viewed at 60 cm. (less than 1° visual angle). A paper-punch-tape unit controlled the 2 Kodak Carousel RA950 projectors which presented the proper memory sets and probe items. An electronic clock (accurate to 1 msec.) measured *S*'s RT to the probe item. An Iconix timing system was used to control the several intervals and stimulus durations.

RESULTS

Each *S* contributed 10 positive RTs (excepting errors and machine failures) to

TABLE 1

Note. Abbreviations: RT = reaction time; RE = relative errors

each of the cells in Table 1 for each similarity condition (acoustic similarity or dissimilarity). Medians of these scores were taken, while all further measures of central tendency were derived by use of arithmetic means. Table 1 shows the average correct RTs and percent errors for each condition, collapsed across both *S*s and similarity conditions.

Error analyses. The attempt to maintain a low error rate was shown to be successful by the 2.31% average error rate for match conditions and 8.74% for no-match conditions. The error rate data provide little additional information beyond that shown below by an analysis of RTs. It is important, however, to note the lack of significance of the acoustic similarity variable in terms of errors, $F\ (1, 23) = 2.96$, $p > .10$. This suggests that the comparison of RTs for the levels of acoustic similarity is valid.

Reaction tim [illegible] A detailed analysis of no-mat [illegible] is difficult because such resp [illegible] not be categorized as arising from [illegible] either the active or inactive men [illegible] It was expected that no-match [illegible] would be slower than match res [illegible] due only to the lower probabili [illegible] rence, and this expectation w [illegible] orted (no-match grand $M = 720$ [illegible] match grand $M = 543$ msec.).

An examinat [illegible] tch responses shows that the [illegible] in effects were significant at [illegible] mory system, $F\ (1, 23) = 4$ [illegible] 083; type of match, $F\ (1, 2$ [illegible] $= .077$; and memory load, [illegible] 13, $\omega^2 = .272$. Also, 2 first-ord [illegible] reached significance: Mem [illegible] $\times$ Type of Match, $F\ (1,$ [illegible] and Memory System $\times$ Mem [illegible] $(2, 46) = 3.63$.

The significan [illegible] main effects supports the re [illegible] merous prior studies. First, [illegible] superiority of active set prob [illegible] 9 msec.) over inactive set prob [illegible] ec.) was found earlier by Ster [illegible] al. (1969) and Forrin and Mori [illegible] 69). This distinction between active and inactive memory is supported by the fact that, in a postexperimental questionnaire, 23 of 24 *S*s reported not rehearsing the inactive set items.

Second, the main effect of type of match shows that physical matches (535 msec.) were made faster on the average than associational matches (551 msec.). Posner and Keele (1967), Posner et al. (1969), and others also found this difference. The magnitude of the difference found here (16 msec.), however, is smaller than that found by Posner and Mitchell (1967). This is due to the use here of the mixed-list procedure (Posner et al., 1969), inclusion of some analogue matches, the 1-sec. interstimulus interval, and the inclusion of associational–physical differences from both active and inactive memory set probes.

Finally, the characteristic increase in RT with an increase in memory load (Sternberg, 1966) is evidenced in the significant main effect of memory load.

The significant Memory System × Memory Load interaction, illustrated in Figure 1, suggests that the slopes of the 2 functions are not parallel. The best-fitting linear equations are

RT = .440 + .068 (H_c) Inactive Memory

and

RT = .417 + .047 (H_c) Active Memory.

It is important to note that the H_c scale of the number of items in memory is an equal-interval log transform scale. The H_c metric is a Shannon statement (log) of central processing uncertainty which is determined primarily by memory load (see Briggs et al., 1971). Such a scale is not without precedent (Briggs et al., 1971; Nickerson & Feehrer, 1964) and more important, the data overall are better fitted in this manner than by a linear scale.

The prediction that the type of information used in the comparison process will be a function of the particular memory system involved (active vs. inactive memory) is supported by the significance of the Type of Match × Memory System interaction. This interaction is plotted as a function of memory load in Figure 2, and indicates that the main effect of type of match was due to the difference between associational and physical matches in active memory. For this reason the physical and associative match functions for inactive memory,

RT = .438 + .066 (H_c) Physical

and

RT = .443 + .069 (H_c) Associational,

are plotted as a single regression equation in Figure 2.

Thus, the data in Figure 2 support the major prediction that the information used to match stimuli in this task is a function of the memory system involved. Further support comes from the contribution of the significant type of match main effect and from the Type of Match × Memory System interaction. These effects show that physical matches are faster than associational matches, but that this difference occurs in the active memory system. Thus, only associational matches are involved in the inactive memory system, while both types of matches occur in active memory.

The fact that neither Type of Match × Memory Load nor any other higher order interactions involving both of these variables was significant indicates that the difference between associational and physical matches in the active memory set is constant across memory load and thus the functions are plotted as best-fitted parallel lines in Figure 2.

Neither the main effect of acoustic similarity, F (1, 23) = .34, nor any of its

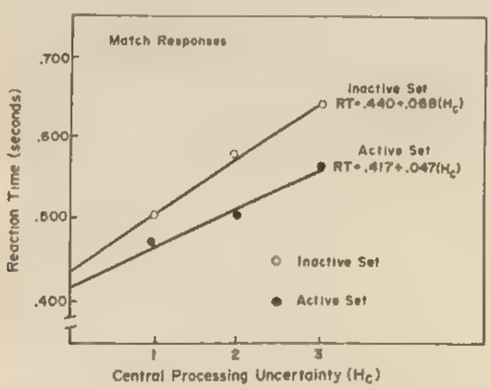

FIGURE 1. Average "match" reaction times (RTs) as a function of central processing uncertainty (H_c) with memory system as the parameter.

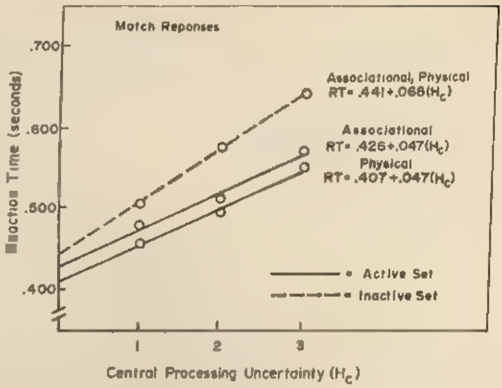

FIGURE 2. Average "match" reaction times (RTs) as a function of central processing uncertainty (H_c) and memory system with type of match as the parameter.

interactive patterns approached significance. It was expected that only the associational matches would be affected by acoustic confusability, and such an effect would serve to converge on the representational differences presumably existing in the different memory systems. If it is assumed that acoustically mediated associations are stored in inactive memory, then it follows that these associations would effect RTs to associational matches in active memory more so than physical matches in active memory. Table 2 revealed that this did not occur. In fact, these data show that that which mediates matches in inactive memory must be operating at least as much in active memory physical matches as in active memory associational matches.

Discussion

Previous studies have loaded what is presumably active and inactive memory in character classification tasks (Forrin & Morin, 1969; Sternberg et al., 1969). It was suggested that differences between these studies might be artifacts of control procedures, such as practice, familiarity, overlap of memory sets, etc. The present study sought to achieve proper control over these variables and determine other and possibly more meaningful explanations for differences in active and inactive memory probe RTs. The following major predictions were made: (*a*) inactive probe RTs are slower than active probe RTs, (*b*) the rate of processing in inactive memory is slower than in active memory, (*c*) both associational and physical matches are made in active memory, and (*d*) only associational matches are made in inactive memory. Support for these predictions is provided in Figure 2. These data suggest that the information stored in active memory is such that both associational matches and physical matches are possible. This in turn implies that visual information, which is more or less isomorphic with the stimulus, is represented in what is presumed to be active memory and is more efficient for use in matching than the associational information. Further, the data suggest that visual information becomes relatively less efficient than the associational information in inactive memory or it must be retrieved in a recoding operation. Thus, *Ss* are able to select and to use visual information when searchi[...] memory in a recognition task; but, [...]tive memory is searched, they are l[...] to use such information.

effect. Here, the memory sets were heterogeneous, i.e., each set could contain both upper- and lowercase letters. Thus, if the memory items are recoded (as Swanson et al. suggested) this must be done on an individual basis. That is, all memory items cannot automatically be recoded given the probe item; each recoding must be based on a comparison of each memory letter with the probe.

Figure 3 diagrams several possible physical and associational match conditions. Its purpose is to illustrate associational–physical match differences in terms of the number of recoding operations. Several points must be considered in examining this figure. First, the matching memory item is shown always in the "final" position. There is neither evidence in this experiment that a serial scan exists, making this the final position, nor that the scan is exhaustive. Also, appearance of the probe in other positions changes the numerical values in the figure but not the difference or conclusions. In sum, the figure involves several noncritical, simplifying assumptions. Second, by definition, associational matches require recoding. This recoding occurs whenever a memory item and the probe item do not match in terms of physical identity. That is, both a (memory item) – A (probe) and D (memory item) – A (probe) require recoding. Thus, for example, in Figure 3 when ab is presented as the memory set and A is the probe, 2 recoding operations are necessary. The third important point is that the difference between associational and physical matches is represented as recoding operations and the number of such operations is constant (difference = 1) regardless of the number of items in the memory set. It is proposed that this constancy yields the intercept difference between associational and physical matches and that the magnitude of the difference (19 msec.) is due to the necessity of one additional recoding for the associational match situation.

The slope difference between active and inactive memory functions is also of concern. First, processing of items presumably stored in inactive memory is slower than processing of active memory probes. This precludes Forrin and Morin's (1969) concept of a match in inactive memory which does not involve search and is independent of the number of items in that memory system. A more reasonable explanation is that items stored in inactive memory must be retrieved prior to comparison with the probe. A parallel retrieval would result in an intercept-only difference between active and inactive memory functions. The slope difference does suggest a serial retrieval of the inactive memory items. The notion that this difference is due to comparison of different codes is rejected because the slope of the associational matches in active memory was not the same as the slope in inactive memory. This introduces the second important point. If recoding of physical into associational form is assumed to involve some interaction with inactive memory (e.g., the association between A and a, be it verbal or visual, is stored in inactive memory), then it would be expected that the estimate of recoding time should be the same as the retrieval of information stored in inactive memory. Figure 2 shows that the recoding time for active memory items is approximately 20 msec. The difference in slopes between active and inactive memory functions is interpreted as an estimate of the serial retrieval time for the inactive memory items. This difference is also approximately 20 msec. Thus, recoding time and retrieval time, which have logical commonalities, are estimated to be of approximately equal duration. This is not to say that recoding and retrieval can replace one another. If this were so, then retrieval of the inactive set items would eliminate the necessity for subsequent recoding, which again, would produce equal slopes in Figure 1.

The third predominant feature in Figures 1 and 2 is the intercept difference between the active memory and inactive memory functions (23 msec.). That this is due to parallel retrieval processes was rejected above (in favor of serial retrieval). Sternberg et al. (1969) suggested that it is due to the additional time required to locate the appropriate ensemble of items in inactive memory. A third possible explanation is that this intercept difference reflects time taken to "identify" or recode the probe item into its associate form. This, however, assumes that active memory is examined first and such identification follows the examination and is prior to search of inactive memory. Such an assumption finds some support in the present study (Table 1); however, earlier it was shown that any recoding of the probe, in connection with active memory, is unlikely due to the mixing of cases in the memory set. Because the same logic applies here, the most parsimonious explanation for the difference in intercept between active and inactive memory

functions is simply the "time to locate" (Sternberg et al., 1969) the inactive set ensemble.

It was predicted that acoustic similarity would increase RTs when associational matches were made. If so, then the association would be presumed to be a verbal one based on an acoustically represented name. The total lack of a significant effect of this variable, coupled with a similar lack of effect of "nameability" on associational matching in a study by Taylor (1969), casts doubt on the hypothesis. There are 2 reasonable alternative hypotheses concerning the nature of the associational match. First, the association may be an abstract verbal code which involves the name of the item but not in acoustical form (Taylor called it a "plan"). Second, the association may be a recoded physical representation. That is, when S is given A to memorize followed by the probe a, he recodes A into a. This recoding is followed by a physical match of a with a. An appropriate manipulation of the visual similarity would address this issue.

INTERACTION OF SIMILARITY TO WORDS OF VISUAL MASKS AND TARGETS

J. ZACHARY JACOBSON [1]

Queen's University, Kingston, Ontario, Canada

Words masked by upright random letters in a wordlike array or by unrelated words are more difficult to read than words masked by other patterns, including strings of complete letters in random orientation. Such a difference was not observed when targets were figures to be identified. This result suggests that a wordlike mask made of letters sets up a reading response that interferes with the processing of a target when the target requires reading.

It has been reported (Jacobson, 1973) that words that are backward masked by unrelated words or by zero-order pseudowords are much more difficult to read than the same words masked by a random-dot Julesz (1971) field. Letters have a higher contour density than the random pattern used in the Jacobson study (squares half as high as the letters), and it was suggested that this localized difference in "grain" produced the aforementioned result.

However, a subsequent study called the contour-density explanation into question. Masks were made by systematically printing one letter on top of another and then erasing a randomly chosen half of each of the 2 letters (see Figure 1B). Strings of such "chimeric letters" were found to be much less effective as masks of words than unrelated words used as masks.[2] It could not be argued that the chimeric-letter masks had less contour density than the words used as masks; if anything, the chimeric letters (which most *S*s said resembled Chinese characters) had a greater contour density than the ordinary letters that comprised the words.

In an attempt to find out more about this puzzling result, a study was done to compare the masking of words by a number of stimuli purposely varied in their similarity to printed English. These masks were: Julesz fields, randomly oriented pieces of letters, randomly oriented whole letters, upright whole random letters (zero-order pseudowords), unrelated words, and words that were associates of the target words. The last condition was included as an internal check for the validity of the study. Words masked by associates are more readily reported than words masked

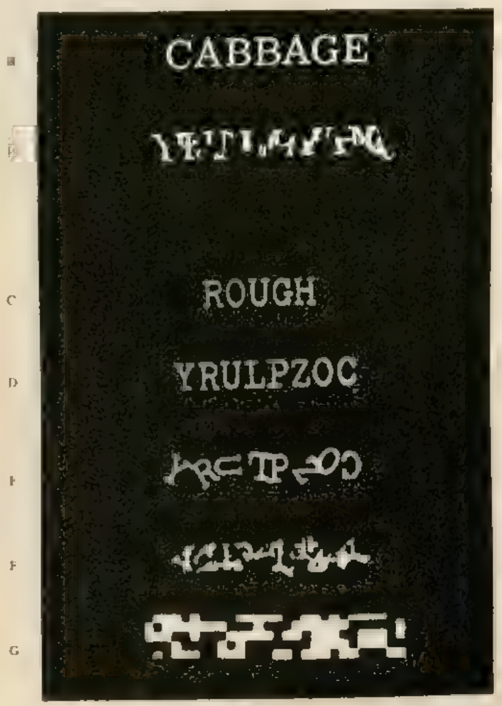

FIGURE 1. Stimuli used in a preliminary study and in Experiment I. (Rows labeled A and B = comparison of word and chimeric-letter stimuli used in the preliminary study; C–G = stimuli used in Experiment I: C = word, D = zero-order pseudoword, E = jumbled letters, F = letter pieces, and G = Julesz field.)

by unrelated words (Jacobson, 1973); if this finding could not be replicated in the present study, the remainder of the data would be suspect. Furthermore, an attempt was being made to continuously vary the similarity of the mask to the target; including associate masks in the study formed a logical extension of that continuum in the direction of increased similarity.

Experiment I

Method. Twenty-five introductory psychology students (20 women and 5 men) served as *S*s.

Letter, word, and letter-piece stimuli were made by photographing typewritten materials with black-and-white film and mounting the negatives as slides for the projection tachistoscope. Thus, *S* saw white capital letters or pieces of letters on a black background. Sixteen associated word pairs were chosen from Arthur's (1969)[3] list of free associates (Figure 1C); unrelated words were the same words mispaired. Zero-order pseudowords (wordlike arrangements of randomly chosen letters) were also used as masks (Figure 1D). Randomly chosen letters in random orientation but arrayed on a line ("jumbled letters") formed another class of mask (Figure 1E). Pieces of letters in random order arranged on a line were yet another sort of mask (Figure 1F).

Strips of Julesz fields from Gregory (1966) were photographed to form the random-dot masks (Figure 1G). Targets for the nonword masks were chosen randomly from the same set of words as targets for word masks.

Each mask was arranged to cover its particular target when projected. A Gerbrands 2-field projection tachistoscope was used to present the stimuli in a dimly lit room. The letters projected on the screen were 4 cm. high with a luminance of 8.0 ± .5 ftL. The background was 2.0 ± .3 ftL. There was no fixation point. The *S*s were seated 3 m. from the screen.

In a pretest procedure, each *S* was shown 1 word for 8 msec. one or very few times (it is not difficult to read unmasked words at this interval under these conditions). Then, as a demonstration of masking, *S* was shown the same word followed 2 msec. later by another word presented for 120 msec. He was asked if he saw the first (target) word, and when he said he did not, he was assured that a word was indeed shown. The masking sequence was slowed down and shown to him again to assure him of that fact. He was told that people for some reason find it difficult or impossible to read a word when it is followed so quickly by a mask. It was further explained that this was to be a study in [illegible] target word would be followed by any of sev[illegible]es of masks, and his task would be to read the target[illegible]

Following the familiarization, 24 randomly ordered trials were given. Targets were always exposed for 8 msec., masks for 120 mse[illegible]

The mask delay needed [illegible] to read a target word correctly was determined [illegible] ascending method of limits. Each trial w[illegible]d with 10 msec. elapsing from the onset of the target to the onset of the mask (Kahneman, 1968, calls this interval stimulus onset asynchrony, or SOA). If *S* could not read the target correctly, the interval was increased by 10 msec. and the seque[illegible] displayed again. To warn *S*, *E* said "ready" be[illegible] each sequence. The *S*s used this warning time [illegible] fixate that part of the screen where the stimuli w[illegible] presented. The procedure was repeated, inc[illegible] interval by 10 msec. each time, until th[illegible] read correctly. The delay of the mask [illegible] *S* read the target word correctly wa[illegible] the dependent variable.

Results. An anal[illegible] variance was conducted on the da[illegible] *S*s became slightly more facile w[illegible] 4 repetitions of each mask condition, [illegible] a mean SOA of 43 msec. on the fi[illegible]etition of each mask condition to 36 [illegible] on the fourth, $F(3, 72) = 3.64$, $p <$ [illegible] There was no apparent interaction between mask condition and repetition. Mean SOAs when the targets were read under the various conditions were, in order of less to more similarity between mask and target: Julesz-field mask, 36 msec.; pieces of letters, 32 msec.; jumbled-letter mask, 36 msec.; 0-order letter sequences, 53 msec.; unrelated words, 48 msec.; and associated words, 33 msec. (See Figure 2).

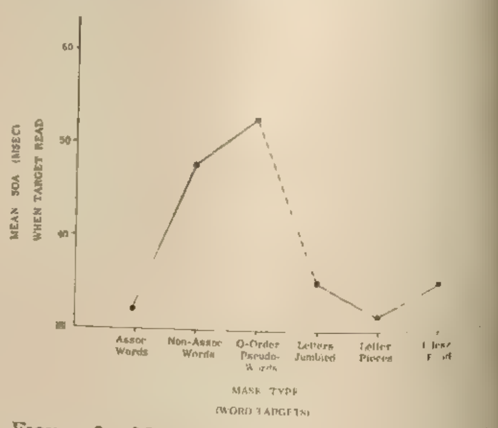

FIGURE 2. Mean stimulus onset asynchrony (SOA) when the target was read correctly: Experiment I.

[3] A. Z. Arthur. Queen's norms for responses to 100 words from the Kent-Rosanoff Word Association Test. (National Research Council of Canada Project APA 0269). Unpublished manuscript, Queen's University, Kingston, Ontario, Canada, 1969.

Individual comparisons with regard to mask treatments were done on the data. They showed that there were 2 separate kinds of masks: those that appeared like or actually were words, and those that did not appear like words, regardless of whether they were made of letters or not. Targets masked by unrelated words and by zero-order pseudowords were more difficult to read than those masked by jumbled letters, letter pieces, and Julesz fields, F (1, 24) = 60.0, $p < 10^{-5}$. There were no reliable differences among words masked by jumbled letters, letter pieces, or random dots. There was no reliable difference between words masked by unrelated words and those masked by zero-order pseudowords. There was a reliable difference between the associated and nonassociated mask conditions, F (1, 24) = 16.04, $p <$ .0008. This comparison is not orthogonal with the rest and is only presented to demonstrate that a previously noted effect was also present for these *S*s.

Discussion. Again, differences in grain cannot explain the results. Contour density was controlled in the jumbled-letter and letter-piece masks by, in the first case, centering each randomly oriented letter physically where it would have appeared if it had been a zero-order pseudoword. A similar procedure was used for the letter pieces except that 2 letters were centered in each position and a random half of each was erased. Thus, contour density was held constant across word, zero-order, jumbled-letter, and letter-piece masks.

The crucial variable seemed to be the arrangement of upright letters in a wordlike array, regardless of whether the letters actually formed a word. An after the fact explanation of this result might be that a reading set is triggered by a mask that is a word or by letters arrayed as a word, and that reading or attempted reading of the mask interferes with the reading of an unrelated target.

If this were true, the relative differences in interference with the target should be limited to reading the target word (or identifying its letters, perhaps), but not to recognizing some other property of it. To test this, another study was done in which the same masks were used, but the targets were rows of shapes for *S*s to identify. The sharp distinction between zero-order masks and the rest of the nonword masks might not occur under the foregoing suggestion.

Experiment II

Method. Sixteen students in introductory psychology, 12 women and 4 men, served as *S*s.

New targets were made of rows of squares, triangles, circles, diamonds, or arrowheads the same size as letters and arrayed in a line; each target contained only 1 sort of shape. These were masked by the same zero-order pseudowords, jumbled letters, letter pieces, and Julesz fields used in the last study. As before, trials in which words were masked by related and unrelated words were included as an internal check of the results.

Again, each *S* was presented each sort of trial 4 times. The procedure was the same as that used in Experiment I.

Results. As before, *S*s improved steadily from the first trial in each condition to the last. Mean SOA was 70 msec. on the first trial and 54 msec. on the last, F (3, 45) = 7.35, $p <$ .001. There was no interaction of repetition and mask type.

Mean SOAs when the shapes were correctly identified were: Julesz-field mask, 47 msec.; letter-piece mask, 51 msec.; jumbled letter mask, 59 msec.; and zero-order mask, 55 msec. There was no apparent difference between zero-order pseudowords on the one hand and jumbled letters, letter pieces, and Julesz fields on the other, F (1, 15) = .5342, p = .52. As before, associated targets were easier than unassociated targets, 42 msec. vs. 79 msec., F (1, 15) = 30.42, p = .0002.

There was a reliable tendency for shapes masked by letter pieces to be more readily reported than those masked by jumbled letters, F (1, 15) = 11.5, $p <$ .004.

Discussion. The *S*s experienced more difficulty identifying word targets in the second study than in the first. It is likely that this was due to the uncertainty present in the second but not in the first study as to whether a particular target was a word or a row of shapes.

It is obviously not possible to state from the observed absence of a difference in identifying shapes when masked by zero-order pseudowords relative to all other masks that no such difference exists. Nevertheless, it seems reasonable to say that such a difference, if it does exist, is much less marked than when the targets are words. This tends to confirm the

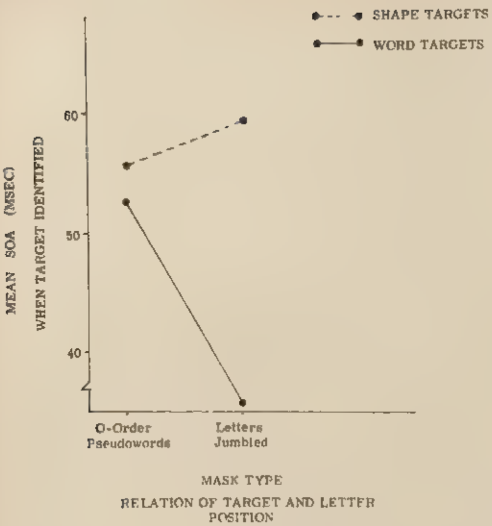

FIGURE 3. Relation of identification of words and shapes when masked by zero-order pseudowords and jumbled letters. (SOA = stimulus onset asynchrony.)

hypothesis that the wordlike arrangement of the mask sets up a process or response that interferes with the identification of a target when that target requires reading, but not otherwise.

There is no inconsistency between this explanation and the fact that words masked by associates were more readily reported than words masked by nonassociates and by zero-order pseudowords. This result cannot be ascribed to guessing, and the explanation that has been suggested is that it is a perceptual effect involving memory traces of the target and mask words (Jacobson, 1973). The memory traces of 2 associated words involve large networks that include many of the same circuits or units. The sets of circuits ("lattices") representing 2 unassociated words in memory would not have as high a degree of mutual inclusion among their elements. Thus, while masking a word by another word interferes with the processing of the target, the activity set up by the mask—if it is an associate of the target—tends to partially restimulate the target's trace. A word masked by an associate, then, needs less of an input of energy containing the target information before it can be identified than the same target word would need if it were masked by an unassociated word.

In the present study, this facilitation by association occurred and effectively countered the interference created by the wordlike appearance of the associated mask. As a result (when the target is a word) there are 2 series of masking stimuli—a wordlike series in which association is an effective aid to recognition, and a nonwordlike series of masks in which word association obviously cannot operate.

Turvey (1973) has suggested that there are 2 kinds of visual masking, one taking place peripherally and one centrally, with markedly different properties. Except for the Julesz fields, all of the masking stimuli used in the present study seem to be the sort that Turvey found to act centrally as well as peripherally. The interaction reported here between mask and target material with regard to their linguistic content (see Figure 3) indicates that, if Turvey is correct, there must be different processes acting even within the central sort of masking. Of course, this assumes that the difference between zero-order and jumbled-letter masks that was observed in Experiment I was effected centrally and not peripherally, but it is difficult to imagine how that could be otherwise.

ORTHOGRAPHIC DISTINCTIVENESS OF CONSONANTS AND RECOGNITION LEARNING

DONALD H. KAUSLER[1] AND EDWARD J. PAVUR, JR.

University of Missouri, Columbia

The effects of varying the distinctiveness of uppercase and lowercase forms of consonants were determined for both single-item (i.e., individual study, or target, items that are later tested for recognition with paired distractors) and multiple-item (i.e., paired study items, one of which is *right*, that are also tested in pairs for recognition of *right* items) recognition learning. Both tasks revealed a greater error rate for consonants of low distinctiveness than for consonants of high distinctiveness.

A feature-analytic hypothesis of single-item recognition learning (e.g., Anisfeld & Knapp, 1968) attributes the false-recognition effect (Underwood, 1965) to a feature-tagging principle. Briefly, sensory and/or semantic features of individually presented study items are presumed to be tagged in some manner during their initial exposure. Recognition of later test items as *old* is then based on their possession of these previously tagged features. Accordingly, the false recognition of *new* items as *old* is likely to be greater when they share sensory and/or semantic features with prior study items than when they are unrelated to prior study items.

A seemingly potent source of sensory features for mediating the false-recognition effect is that of orthography. In a recent experiment by Raser (1972), a number of study items were homophones that were later paired for testing purposes with their homophonic counterparts as distractors. The pairs were either high or low in orthographic distinctiveness (e.g., CLAWS–CLAUSE and FOUL–FOWL, respectively). Also included in the experiment were nonhomophonic study items that were later paired with distractors of either high or low orthographic distinctiveness (e.g., CLOUD–CLEAVE and SOUR–SLUR, respectively). The false-recognition rate (i.e., selecting new intrapair members as *old* study items) was contrasted for test pairs of varying disinctiveness. Sharing of tagged orthographic features should, of course, be greater when the *old–new* members of test pairs are low in distinctiveness than when they are high. In agreement with this hypothesis, Raser found that orthography had a significant effect on the rate of false recognitions. In fact, the effect was more pronounced than that found for shared phonemic features.

Similar findings have been reported for the multiple-item, or verbal discrimination, recognition learning task. Kausler (1973b) discovered slower acquisition for paired homophones (i.e., one member of each pair functioned as the *right* item, the other as the *wrong* item) of low orthographic distinctiveness than for paired homophones of high orthographic distinctiveness. Schulz and Lovelace (1972) found a parallel effect when either homophones or nonhomophones of high and low orthographic distinctiveness functioned as interpair *right* and *wrong* items. These results support the general hypothesis that multiple-item recognition learning, like single-item recognition learning, is mediated by a feature-analytic–feature-tagging process (Kausler, 1973a, 1973b, in press).

The present experiments provided a further test of the effects of orthographic distinctiveness on recognition learning. Specifically, the test involved distinctive features at the level of graphemic content, rather than distinctive features at the more molar level of distinctive orthography (i.e., letter content, word length, etc.—as is the case when words serve as items). The

[1] Requests for reprints should be sent to Donald H. Kausler, Department of Psychology, University of Missouri, 209 McAlester Hall, Columbia, Missouri 65201.

present study items were consonants scaled for the distinctiveness of their upper- and lowercase forms. Upper- and lowercase forms of the same letter have identical phonemic features, and, presumably, highly overlapping semantic features as well. Consequently, when one form of each letter is a study item and the other form a paired test distractor, intrapair discriminations are likely to be accomplished through whatever distinctive graphemic features were tagged during the original study phase. Since consonants vary widely in the distinctiveness of their upper- and lowercase forms (e.g., G, g vs. Z, z), their hit rates in single-item recognition learning should reflect this variation. A similar effect should occur when the upper- and lowercase forms function as intrapair *right–wrong* (or *wrong–right*) members of a multiple-item recognition learning task. Experiments I and II provided tests of this hypothesis for the single-item and multiple-item tasks, respectively.

Experiment I

Method

Subjects and design. Forty students in general psychology classes at the University of Missouri, all of whom were naive with respect to prior participation in recognition learning experiments, served as *S*s. They were assigned alternately to 2 groups ($n = 20$) that differed only in the instructions (standard vs. experimental) given prior to the first study phase. Distinctiveness was a within-groups variable, with half of the study list composed of consonants previously rated (by a separate group) as being high in upper- and lowercase distinctiveness and the other half of consonants previously rated as being low. Thus, the design was a 2×2 factorial, with one between-groups and one within-groups variable.

Materials and lists. Upper- and lowercase forms of the 20 consonants had been rated earlier by 112 *S*s (general psychology students) for their physical distinctiveness on a 9-point scale (1 = very distinctive, 9 = very similar). Mean ratings ranged from 3.16 (G vs. g) to 8.45 (Z vs. z). For purposes of this study, the consonants were divided at the median into a high distinctiveness (HD) set (G, Q, D, R, N, H, B, L, T, and M—in order of decreasing distinctiveness) and a low distinctiveness (LD) set (Z, V, P, X, W, S, C, K, J, and F—in order of increasing distinctiveness). The uppercase forms served as study items for 5 HD and 5 LD consonants; the lowercase forms served as study items for the remaining 10 consonants. For greater generalization of results, 2 variants of the study list were employed. In the first, the uppercase form of the odd-numbered consonants (as ranked from most to least distinctive) and the lowercase form of the even-numbered consonants were study items. In the second variant, the lowercase form of the odd-numbered consonants and the uppercase form of the even-numbered consonants became the study items. The *S*s in the 2 instructional groups were assigned alternately to the 2 list variants. In addition, 2 different random orders for presenting the study items were employed per trial in each list variant. Neither list variation nor order of presentation were later found to influence hit rate. Consequently, these factors were pooled for the analyses reported later. Study slides and subsequent test items were typed on the same IBM Selectric typewriter.

List length was extended by including 30 2-digit numbers as additional study items. The first 5 and the last 5 study items were always numbers; the remaining 40 items alternated between consonants and numbers.

Procedure. All *S*s were fully informed as to the composition of the study list. That is, they knew that uppercase consonants, lowercase consonants, and numbers would be exposed, and that they were to remember the items for a subsequent memory test. They were further informed that uppercase and lowercase consonants would always appear on the right and left sides of the screen, respectively. This procedure was followed in order to assure perception of the appropriate case form of the less distinctive consonants. The standard instructional group received only the above information. The experimental instructional group received additional information suggesting that a useful device for memorizing the consonants would be to form an image of each consonant that emphasized its distinctive features. It was anticipated that these instructions would reduce the disparity in hit rates attributable to graphic distinctiveness.

There were 2 study–test trials. On the study phase of each trial the individual items were exposed, via a Kodak Carousel projector, at a 2-sec. rate, with a .9-sec. interitem interval. Test items were presented in a test booklet, with a separate page for each trial. Each *old* consonant item was paired with its upper- or lowercase counterpart as a distractor, and each *old* number with a *new* number as a distractor. Correct items appeared equally often on the right and on the left of the test pairs. Two different random orders of pairs were used per trial with each of the list variants described earlier. Order was again found to be unrelated to hit rate, and the different orders were pooled for the main analyses. For each of the 50 pairs, *S* encircled the *old* item, and rated the confidence of his judgment on a 5-point scale. The test phases were self-paced.

Results and Discussion

Means and standard deviations for total errors on the 2 trials are given in Table 1.

The main effect for distinctiveness was statistically significant, F (1, 38) = 4.75, $p < .05$. As hypothesized, the error rate was greater for LD consonants than for HD consonants. Neither the main effect for instructions nor the Instructions × Distinctiveness interaction effect approached significance, Fs (1, 38) < 1. It is conceivable that imaginal encoding is the dominant means of processing graphic features for tagging purposes. If true, further instruction to use this strategy would be redundant.

An additional question concerns the distribution of errors across the full continuum of the distinctiveness variable. The overall correlation between distinctiveness ratings and errors per consonant approached statistical significance, ρ (20) = .42, $p < .10$. The failure to find a more pronounced correlation stems from the seemingly nonmonotonic covariation between distinctiveness and error rates. Grouping the consonants into successive sets of 4 consonants each, the total errors per set (ranging from most to least distinctive) were 42, 61, 43, 67, and 77. Thus, the departure from an otherwise regular increase in error rate with decreasing distinctiveness occurred for consonants of intermediate distinctiveness.

The confidence ratings revealed a pattern that paralleled that found for error rates, and they offered no additional insights into the processes underlying the effects of distinctiveness. Consequently, these data will not be reported here.

TABLE 1

Summary Statistics for Total Errors in Single-Item (Experiment I) and Multiple-Item (Experiment II) Recognition Learning

Distinctiveness	Instructions: Imagery M	Imagery SD	Standard M	Standard SD
Single-item recognition				
High	3.00	2.49	3.25	2.63
Low	4.40	2.85	3.85	2.28
Multiple-item recognition				
High	8.25	5.49	6.30	5.33
Low	13.15	8.66	9.95	8.16

Experiment II

Method

The design and general procedure followed that of Experiment I, but with appropriate modifications for the shift from a single-item to a multiple-item task. There were again 40 *S*s, 2 instructional conditions as a between-groups variable, and 2 levels of distinctiveness as a within-groups variable. Each experimental list contained 20 pairs of upper- and lowercase consonants (without additional filler pairs). One member of each pair was designated the right item. Half of the right items were uppercase forms (5 HD and 5 LD), the other half, lowercase forms (5 HD and 5 LD). Two variants of the list were employed, with the *right* and *wrong* members of pairs reversing functions across the variants. There were 8 study–test trials. On the study phase of each trial the individual pairs were exposed, via a Kodak Carousel projector, at a 2-sec. rate and .9-sec. interpair interval. The *right* member of each pair was underlined. Test pairs were presented in a test booklet, with a separate page for each trial. The *S*s indicated *right* items by encircling one member of each pair (self-paced). Different random orders were employed across study and test phases, and standard control procedures for verbal discrimination research were applied (e.g., *right* items appeared equally often on the spatial right and left for each study and test phase). Finally, to assure familiarity with the procedure, practice on the experimental list was preceded by 2 trials on a practice list composed of upper- and lowercase pairs of vowels.

Results and Discussion

Means and standard deviations for total errors on the 8 trials are given in Table 1. The main effect for distinctiveness was again statistically significant, F (1, 38) = 21.16, $p < .001$, with the error rate once more being greater for LD consonants than for HD consonants. As in Experiment I, neither the main effect for instructions nor the Instructions × Distinctiveness interaction effect approached significance, Fs (1, 38) = 1.60 and <1, respectively. If anything, there was a slight trend toward more errors under imagery instructions than under standard instructions.

The distribution of errors across the full continuum of the distinctiveness variable was examined further, this time in the context of multiple-item learning. The overall correlation between distinctiveness

ratings and errors per consonant attained statistical significance, ρ (20) = .50, $p < .05$. The total errors per set of 4 consonants (ranging from most to least distinctive) were 105, 157, 122, 170, and 199. Thus, the locus for the departure from a monotonic relationship coincided with that found for single-item recognition learning, i.e., with consonants of intermediate distinctiveness.

The extraction and concomitant tagging of distinctive graphemic features appear to be important components of both single-item and multiple-item recognition learning. It is this commonality of processes that presumably underlies the commonality of the functional relationships demonstrated in the present experiments. Thus, the present results add further support to the basic continuity between variants of recognition learning. In both variants, distinctive features of items are tagged, most likely by frequency-of-response cues (Kausler, 1973a, 1973b), during study phases. The tagged features are components of target items in the single-item task and components of *right* items in the multiple-item, or verbal discrimination, task. Subsequent discriminations are based on the presence of t[illegible] [illegible]ed features for target items, but n[illegible] [illegible]stractor items, in single-item tests, [illegible] [illegible]*ght* items, but not for *wrong* items, [illegible] [illegible]iple-item tests.

STUDY AND RETRIEVAL INTERVAL EFFECTS IN PAIRED-ASSOCIATE LEARNING

ALFRED A. BAUMEISTER[1] AND DORIS KISTLER

University of Alabama

Four groups of *S*s learned a list of paired associates (consonant–consonant–consonant: digit) under 4 combinations of study and retrieval times (2 vs. 6 sec.). Other *S*s were allowed to pace themselves during the study phase of the task. Transfer tests were carried out to measure cue selection and trigram integration. The major results were as follows: (*a*) study time up to 6 sec. influences rate of learning, (*b*) study time and retrieval time produce interactive effects on learning, (*c*) longer retrieval times are associated with a greater amount of single-letter selection and less stimulus integration, and (*d*) study time has little effect upon cue selection.

Studies of variations of item exposure duration have focused for the most part upon the rate rather than upon the process of acquisition. Much of the research pertaining to presentation interval has been generated by Bugelski's (1970) *total-time hypothesis* which states that the time required to learn a given amount of material is a constant regardless of how that time is spread across trials. The amount learned is a function of the total time committed to learning, within limits.

Actually, the total-time hypothesis is a generalized expression of a relationship between time available for learning and *performance*. It does little by way of elucidating what is learned and the way in which learning proceeds. Clearly, the manner in which time is distributed during a learning trial may differentially affect encoding, storage, and retrieval processes. Accordingly, the major focuses of the present investigation are upon the effects of the distribution of time in relation to cue selection and stimulus integration and the reciprocal interaction of acquisition and retrieval processes.

Much of the support for the total-time hypothesis has come from paired-associate (PA) learning studies, primarily of the anticipation variety. Cooper and Pantle (1967) noted that the functional time, insofar as the hypothesis is concerned, is probably the study interval. An implication of this conclusion is that rehearsal is the critical process affected by variations in study time.

Recently, a number of experiments have been reported that raise serious questions concerning the validity of the total-time hypothesis. Izawa (1971) has argued that the anticipation procedure of PA learning confounds the effects of study and test intervals. There is good reason to assume that acquisition and retrieval are qualitatively different processes. Izawa found that the way in which time is distributed in the study–test method produces effects that are different from those observed when anticipation procedures are employed. Stubin, Heimer, and Tatz (1970) also raised a number of conceptual and methodological criticisms of experiments that purportedly provide support for the total-time hypothesis. Using the study–test method, they reported that shorter presentation times are more efficient than longer presentation times. That is, doubling the number of exposures of a pair produced more effective performance than doubling exposure time per se. A similar conclusion was reached earlier by Johnson (1964).

The results of these and other investigations suggest the possibility that variations in study time may lead *S* to adopt different acquisition strategies. Furthermore, although acquisition and retrieval phases can be experimentally separated in the study–test method of PA learning, there is

the possibility that time constraints placed on S during retrieval may affect his encoding of the stimuli.

In the present experiment, study time and retrieval time were varied factorially. The stimulus terms were consonant trigrams, the responses were digits. Transfer tests were made to determine degree of letter selection and trigram integration that occurred during learning.

Method

Subjects. The *S*s were 75 undergraduate volunteers from introductory psychology courses at the University of Alabama. None had been previously involved in PA learning experiments.

Materials. The learning materials consisted of 6 pairs with consonant trigrams as stimuli and single digits as responses. The pairs were as follows: PMD:7, KHB:5, VLT:6, GWS:4, JYC:8, and FRN:9.

Apparatus. The learning and transfer materials were presented to S on an inclined viewing console, 53.3 cm. long and 27.9 cm. high, in which 4 one-plane display projectors were mounted. The viewing surface for each projector was approximately 2.5 × 5 cm. Three projectors, containing letters, were mounted side by side. The fourth projector, containing the digits, was placed 5 cm. to the right of the other 3. A series of electronic timers and stepping relays were used to program presentation of the materials. All intervals and sequences were automatically controlled.

Procedure. The study–test (retrieval) method of PA learning was employed. Each of 60 *S*s was randomly assigned to 1 of 4 combinations of duration of study and retrieval intervals. The study and retrieval durations were either 2 or 6 sec., with the 4 combinations designated as 2–2, 2–6, 6–2, and 6–6. The number on the left refers to study interval, the number on the right to retrieval interval.

The remaining 15 *S*s were assigned to a self-paced study condition. The S held a switch that enabled him to change study items. These *S*s were given 2 sec. to retrieve the digit. Latencies were recorded for each study item.

Each S was read standard instructions for study–test PA learning. A complete trial consisted of one presentation of all 6 pairs and the 6 stimulus terms. A buzzer was used to cue S prior to the test phase within a trial. A constant 5-sec. interval separated study and test phases. Four different orders of items in both study and test were administered to prevent serial learning.

The criterion of learning was 2 successive perfect recitations of the list. Immediately upon reaching criterion, transfer tests were given. In the first transfer test, S was shown the 18 letters, 1 at a time, for 10 sec. each, and asked to recall the appropriate digit. Following digit recall, *S*s were again shown the 18 consonants and asked to identify the "missing" letters. Each was presented for 10 sec. Four different orders were used for individual letter presentation. The letters appeared on the console in the same position as in original learning.

Results

Original learning. Learning performance was expressed in terms of trials to criterion. Mean trials were 8.6, 6.1, 4.9, and 5.3 for the 2–2, 2–6, 6–2, and 6–6 groups, respectively. A 2 × 2 analysis of variance revealed a significant interaction effect, $F\ (1, 56) = 5.2$, $p < .05$. The *S*s learning under the short study and retrieval intervals (2–2) required more trials to reach criterion than *S*s in other groups. There was no significant difference between any of the other conditions.

The self-paced *S*s required a mean of 4.6 trials to attain the performance criterion. Analysis of variance involving just the groups given the 2-sec. retrieval interval revealed a significant effect, $F\ (2, 42) = 10.8$, $p < .01$. The 6-sec. and the self-paced groups did not differ and both were superior to the 2-sec. study group. The mean latency to respond during the study interval for the self-paced group was 15.2 sec/item. However, these *S*s were apparently able to differentiate learned from unlearned items in the study phase. They selectively took more time with items that they had failed on the previous trial,

TABLE 1

Mean Number of Single-Letter Solutions by Study Time and Retrieval Time

Retrieval	Letter position 1	2	3
	2-sec. study		
2 sec.	1.3	.2	.1
6 sec.	1.7	.2	0
	6-sec. study		
2 sec.	1.0	.1	.2
6 sec.	2.2	.1	.3
	Self-paced		
2 sec.	1.5	.1	.5

F (1, 14) = 10.2, $p < .05$. However, total time was not significantly correlated with trials to criterion (r = .08).

Cue selection. The double criterion method of scoring single-cue selection described by Berry and Baumeister (1971) was employed: A correct digit recall to one and only one of the letters of the trigram was scored as single-letter selection. Table 1 presents the mean number of single-letter solutions for various groups. A 2 × 2 × 3 analysis of variance including study time, retrieval time, and letter position was applied to these data (excluding the data from the self-paced condition). As expected, letter positions were differentially effective recall cues, F (2, 112) = 46.0, $p < .01$. More correct recalls were made to the first letter than to either of the other 2 letter positions. The main effect of retrieval time, F (1, 56) = 5.1, $p < .05$, and the Retrieval Time × Letter Position interaction, F (2, 112) = 3.6, $p < .05$, were significant. More single-first-letter solutions occurred under the 6-sec. retrieval interval than under the 2-sec. condition.

A separate 3 × 3 mixed analysis of variance comparing the self-paced, 2-sec., and 6-sec. study conditions across letter positions yielded a significant effect of position, F (2, 84) = 17.8, $p < .01$. Again, it was the first letter of the trigram that was the most effective recall cue.

Trigram integration. In the final phase of the experiment, *S*s were presented one letter of the trigram and requested to reproduce the remaining letters. The number of letters recalled was totaled for each individual. Means for the 2–2, 2–6, 6–2, and 6–6 groups were, respectively, 22.6, 17.1, 24.9, and 17.3 letters correctly recalled. An analysis of variance yielded a significant effect for retrieval time, F (1, 56) = 7.9, $p < .01$. This result can be interpreted to mean that significantly greater integration of the trigram occurred under the shorter retrieval interval.

The mean number of letters reproduced in the self-paced study condition was 21.5. An analysis of variance comparing the self-paced with the 2–2 and 6–2 groups failed to yield a significant effect, F (2, 42) = 1.49. Length of study time by itself seems to have little effect on trigram integration.

Discussion

The results demonstrate that variations of study time and retrieval time may produce interactive effects upon PA performance. The *S*s given 6 sec. to study each pair reached criterion faster than those who were given 2 sec. of study time. However, in the case of those individuals who viewed the pair for only 2 sec. but who also were provided relatively long (6 vs. 2 sec.) retrieval time, the detrimental effects of the brief study interval were mitigated considerably. This finding implies the existence of some sort of information feedback mechanism from retrieval to storage process in PA learning. As time constraints are relaxed in the retrieval phase, different strategies appear to be utilized during storage. Loftus and Wickens (1970) have reached a similar conclusion based upon their study of incentive cuing in the retrieval phase of PA learning.

Tests for letter selection and letter reproduction indicate that variations in retrieval interval influence encoding strategies. In particular, it appears that, given greater time to retrieve the response term, college students are more inclined to select the first letter of a consonant trigram as the functional cue. Not only was there a greater amount of single-letter selection in the 6-sec. retrieval condition, relative to the 2-sec. condition, but there was also less integration of the stimulus compound under the former condition.

Although these results may, at first, seem to be at variance with what one might expect on a commonsense basis, we believe that when the test or retrieval phase is brief, *S*s do not have sufficient time to actively adopt a cue-selection strategy. What is learned during the acquisition phase in the PA task is influenced by time constraints placed on recall.

The performance of the self-paced *S*s is instructive in this regard. Although they were allowed all the time they wished to study each pair, they were permitted only 2 sec. for retrieval of the response. Transfer tests for digit recall to single letters and for letter reproduction revealed that the self-paced group performed in much the same ways as the other E-paced *S*s in the 2-sec. test condition. Lovelace and Greenberg (1969) have likewise reported that the length of the study interval

(2 vs. 6 sec.) does not affect cue selection in PA learning with consonantal trigrams as stimuli.

Any hypothesis stating that the amount learned is a function of the time given to study is an oversimplification on at least 2 counts. First, study time and retrieval processes are not independent. Secondly, even if overall performance is the same when time is equated, different learning strategies may be employed.

ATTENTION BIAS AND THE RELATION OF PERCEPTION LAG TO SIMPLE REACTION TIME [1]

A. J. SANFORD [2]

University of Dundee, Dundee, Scotland

Previous research suggests that stimulus loudness affects simple reaction time to a greater extent than it affects subjective simultaneity judgments. A question has recently arisen as to whether these results can be attributed to an attention bias like that of "prior entry." An experiment precluding the possibility of this artifact replicated previous results. Some alternative interpretations of the results are briefly outlined.

There is evidence to suggest that a simple phenomenological model is adequate to account for the relationship between visual intensity and simple reaction time (RT). This view supposes that perceptual lag, i.e., the time to perceive a stimulus from its onset, is influenced by stimulus brightness, and that a reaction is initiated as soon as perception of the stimulus has occurred (Roufs, 1963, 1966). That is to say, the effect of stimulus intensity changes on difference in the time of perception is the same as the effect of RT differences. In studies supporting this contention, Roufs (1963) compared the size of the effect of intensity on behavioral RT and phenomenal simultaneity and found that the size of the intensity effect was the same in both cases. Others have suggested that not all of the behavioral RT effect is accounted for by perception lag (Hohle, 1967). This is particularly evident in the case of auditory intensity (loudness). There is evidence that RT is affected to a greater extent by loudness changes than is perceptual latency, as revealed by a perceptual simultaneity task (Sanford, 1971). Indeed, Roufs (1963) has reported a failure to find any effect of auditory intensity on the point of subjective simultaneity for click–flash pairs.

The purpose of the present article is to examine the apparent discrepancy between the effect of loudness on perceptual lag and simple RT using the same paradigm as that of Sanford (1971). Specifically, the design used is an attempt to ensure that the conclusions that have been drawn are not based upon data resulting from an attentional artifact. The task used in the previous study required *S* to watch a quickly rotating pointer move across a circular dial. While *S* was watching the display, an auditory signal was presented, and *S*'s task was to say where the pointer was positioned at the onset of the sound. By manipulating the intensity of the sound, some changes in the reported position of the pointer at onset were obtained, and the results suggested that perceptual lag increased with decreases in stimulus intensity. The increase was, however, much smaller than the increase in behavioral RT measured for the same loudness range. It was argued that, with such a design, behavioral RT and perception lag could be measured under almost identical conditions, thereby minimizing the possibility of differences in intensity effect magnitude resulting from different response criteria. (See Murray, 1970, or Grice, 1968, for a discussion of the response criterion concept.)

The design actually employed entailed the presentation of the different intensities in blocks. However, this may have had a biasing effect on the distribution of *S*'s attention to the two components (visual and auditory) of the task. In particular, it may be argued that the trial blocks in

L					
M	61	37	29	31	32
SD	21	13	15	15	

Note. The L value is derived from the actual pointer position − the observed pointer position.

which extremely close-to-threshold stimuli were employed would cause S to attend more closely to the auditory display than he would for higher signal-to-noise ratios. Although we are only just beginning to construct models of attention bias of this type (cf. Sternberg & Knoll, 1973), the idea that attention bias influences the perceptual lag has long been in existence as the law of prior entry (Titchener, 1908), which states: "The stimulus for which we are predisposed requires less time than a like stimulus, for which we are unprepared to produce its full conscious effect [p. 251]." Stone (1926) and Sternberg and Knoll have demonstrated that simultaneity judgments are influenced by attentional bias in the manner predicted by the prior-entry law.

In the case of Sanford's (1971) pointer test it may be argued that the prior-entry effect could produce the result that the intensity effect under the pointer test was less than that under RT conditions. When blocks of quiet stimuli are being presented, additional attention may be paid to the auditory stimulus, which would, by prior entry, cause the stimulus to be detected earlier than it would were less concentration being devoted to it. Thus, attentional bias runs against the naturally greater detection lag that could be associated with quiet stimuli. When blocks of loud stimuli are used, the converse argument applies. Although detection lags are smaller for loud stimuli, this effect may be offset by less attention being paid to the loud stimuli. The result of these two biases would be to lessen the magnitude of the intensity effect in the clock task. Such a possible bias can only be eliminated by using a design in which the stimuli of differing intensities are presented randomly.

METHOD

Apparatus. The S ($N = 8$ Royal Navy enlisted men) was required to do two tasks, the RT task and pointer task. In the pointer task, Ss had to watch a pointer revolving around a clock face and say just where the pointer was at the time when the onset of the stimulus occurred. The "clock" was a chronoscope graduated in centiseconds, with a 1-sec. sweep. Every tenth-of-a-second was numbered 0, 10, 20 . . . 90. The sweep-face was 8-cm. in diameter, and the face was set centrally into a 14.5-cm.^{2} box. The whole chronoscope was set into a 50-cm.^{2} board. The board was mounted on a table in front of S at a viewing distance of 60 cm. A comfortably bright level of illumination was used and lamps were arranged so that variations over the surface of the clock face were minimal. Stimuli consisted of increments in a background of random noise—intensities, measured by a Dawe sound-level meter coupled to the earphones, were 60 db. for the background rising to 62, 63, 67, and 78 db. for Stimuli 1, 2, 3, and 4. Stimuli were effectively continuous, being terminated by E after S had responded. They were presented binaurally, and had an effectively zero rise time.

On each trial, S watched the pointer, which swept over the clock face once, and a stimulus was then introduced on the second sweep. Temporal uncertainty was thus in the range 1–2 sec. The distribution of stimulus onset points was roughly equally dispersed across the range 1–2 sec.

The RT apparatus consisted of a microswitch arranged on the release-to-react principle for S's nonpreferred hand. Stimulus onset activated a system of decatron timers which ceased counting when S reacted.

Procedure. There were three sessions. In the first session, Ss were acquainted with the stimuli and given some practice at the RT task. In the following two sessions, Ss heard 30 stimuli at each intensity (120 stimuli in all) in a random order. In addition, 24 blank trials were introduced in which no stimulus was presented. The first of these sessions was considered practice. All analyses are therefore based on final-session data. The Ss were instructed to perform the pointer test and the RT test simultaneously, and were told that the pointer test was concerned with visual acuity, and that they were to say where the pointer was when the stimulus first came on. Instructions for RT were standard.

RESULTS

The pointer test scores were made in the following way. A value of *L* (actual pointer position minus the observed pointer position), was obtained for each judgment. The mean of these values was then obtained. The RT and *L* scores are given in Figure 1 and Table 1 and demonstrate the attenuated intensity function obtained in the judgment task.

A simple nonparametric test, Friedman's analysis of variance (Siegel, 1956), was applied to each set of scores and revealed an effect of intensity on RT ($p < .001$) and an effect of intensity on *L* ($p < .001$). The interaction effect was tested by comparing RT–*L* values as a function of intensity and was significant

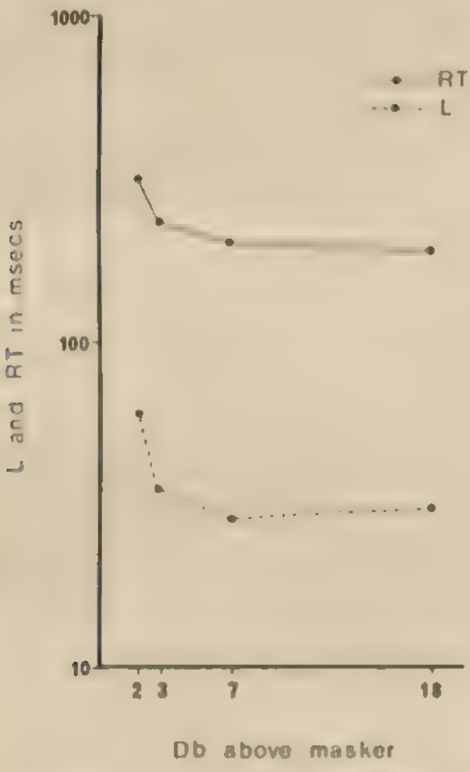

FIGURE 1. Mean values of reaction time (RT) and *L* (actual pointer position − observed pointer position) plotted on a log scale against stimulus intensity. (It is apparent from this that the change in RT is greater than the change in *L*. Statistical analysis was carried out on the untransformed data.)

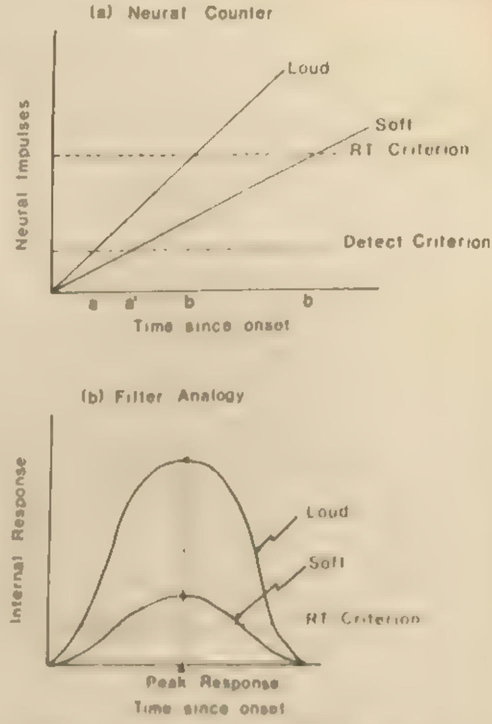

FIGURE 2. (a) Graphical representation of the counter model (e.g., Grice, 1968). (The effect of intensity on the detect-for-judgment [DJ] state, a′ a, is seen to be less than that on the detect-to-react [DR] state, b′ b, because the DJ state criterion requires less evidence than the DR state criterion.) (b) The internal response to a stimulus can also be considered as analogous to the output of a simple filter (Sternberg & Knoll, 1973). (If an event such as the peak internal response is used to trigger DJ states, then if there is any effect of intensity at all it should be less than that obtained in reaction time [RT] tasks, since DR states would be initiated by a variance setting amplitude detector analogous to the criterion of the counter model.)

($p < .001$). Hence, the results show that although intensity influenced *L* and RT, RT was influenced to a much greater extent. (Parametric tests were not used since use of a transform to satisfy parametric assumptions would be incompatible with considering a specified scale of measurement, namely, linear time. The primary interest in this experiment is in the interaction of RT and *L*, and this would be modified by any nonlinear transformation.)

Discussion

The results obtained in the present experiment are substantially similar to those obtained by Sanford (1971). They support the view that the differential effects of stimulus intensity on RT and simultaneity cannot be attributed to an attentional bias interacting with the intensity effect, since this was prevented by the use of random stimulus schedules.

The most general statement which can be made on the basis of the results is that different amounts of stimulus information have to be sampled in order to cause a detect-to-react (DR) and detect-for-judgment (DJ) event to occur. Sanford (1972) suggested that the DR state may well occur at an earlier date than the DJ state. This is based on the argument used in favor of the simple counter model of RT, i.e., that smaller intensity effects reflect less stimulus sampling than larger ones. This is consistent with the view of Murray (1970) and others that the magnitude of an intensity effect is directly related to the lag in stimulus detection, since it reflects criterion level. This is clear from the model shown in Figure 2a where neural impulses are assumed to be counted until a criterion number have been accumulated. Quiet signals are assumed to cause slower neural impulse rates than loud ones. This interpretation is consistent with the findings that *S*s are aware of some of the intensity-dependent delay in RT, when measures are made of subjective ratings of RTs (Sanford, 1970).

Other experimental work comparing intensity functions for RT and simultaneity has recently been discussed by Sternberg and Knoll (1973), who have developed an alternative suggestion that DJ states may be triggered at a later point on the stimulus continuum than DR states. They suggest that the internal representation of a stimulus may be likened to the response of a filter to a step input, Figure 2b. The occurrence of a particular level of input mediates the DRs, while DJs are based on the peak response of the system. Since peak responses occur at the same time for stimuli of different amplitudes, an absence of intensity effect on tasks tapping the DJ system might be expected. However, Sternberg and Knoll do suggest this model for pulsed stimuli only, presumably with a duration less than the time constant of the filter. Whether it can be generalized to stimuli longer than the time constant (as used in the present study) is an open question. If it could be so generalized, it would reflect a detection of asymptote rather than peak. It is, of course, possible that the asymptote of the filter output may be associated with some neural event which could act as a cue for DJ states if the filter model is correct. At this stage, it seems impossible to distinguish between these two views, and Sternberg and Knoll point out that DR and DJ states may be elicited by different aspects of the internal representation of the stimulus in tasks that differ only slightly. The present results merely show that the discrepancy between RT and simultaneity measures of detection latency cannot be accounted for by an explanation based upon attentional bias.

ASYMMETRIES IN JUDGMENTS OF VERTICALITY[1]

PHILIP H. K. SEYMOUR[2]
University of Dundee, Dundee, Scotland

Two experiments are reported in which *S*s judged whether or not the word *above* or *below* correctly specified the location of a dot relative to a picture of a face. In Experiment I, the face was horizontally oriented with its top to the left or right and the dot to the left or right. An analysis of the latency data showed a substantial *same–different* effect and a marginally significant advantage for *above* vs. *below*. In Experiment II, the face was normally oriented or inverted. The normal face was associated with a significant *above* vs. *below* difference and a *same–different* effect. When the face was inverted, both of these effects were eliminated. These results are discussed in relation to recent theories about the verification of spatial locations.

Seymour (1969) reported a study in which *S*s made *same–different* judgments of displays consisting of the words *above* or *below* and pictures of a dot above or below a reference square. The main findings were that reaction times (RTs) were faster for *above* displays than for *below* displays, and faster for *yes* reports than for *no* reports. These findings were subsequently confirmed by Chase and Clark (1971).

Chase and Clark (1971) argued that the *above–below* asymmetry must depend on differences in encoding time for the words *above* and *below* and not on a tendency to scan the display in a top–down direction as had been proposed by Seymour (1969). However, the evidence cited by Chase and Clark was not sufficient to determine this issue. In their Experiment 2 they showed that the *above–below* asymmetry disappeared when the words were replaced by arrows; this alters the task to one of 2-choice responding to the proximity of a dot and arrow/head and appears not to involve a proper comparison of locations. In Experiment 3 they replaced the words *above* and *below* by *present* and *absent*, which were to be matched against a dot that might or might not appear at a constant location within a block of trials; this experiment would bear on the question of focused attention on the upper region of the figure only if the dot signifying present were allowed to occur randomly in the upper or lower locations.

Chase and Clark's (1971) Experiment 4 involved figures in which the dot occurred only in the above location for one group and only in the below location for the other. The *S*s were instructed to infer the below location from *absent*–above in the one case, and above from *absent*–below in the other. In the top-visible condition, the pattern of latencies was similar to that obtained under the normal condition, but substantial alterations occurred in the bottom-visible condition, which Chase and Clark interpreted as an addition to the time required to encode the location above. On the other hand, the top-visible condition did not result in an increase in the time to encode the location below, so that Chase and Clark commented that, "Apparently, subjects normally attend to the upper location of the circle, hence they normally (or often) only *infer* (*circle below square*) in the *BELOW* displays [p. 322]."

Given this latter comment, it appears that Seymour (1969) and Chase and Clark (1971) are in agreement in arguing that attention is often initially focused on the upper region of the figure; a tendency of this kind might delay encoding of *below* displays because of top–down scanning or because of the occurrence of a time-consuming inference. Chase and Clark have added the assumption of a difference in encoding time for the words *above* and *below*, and have argued that this occurs because

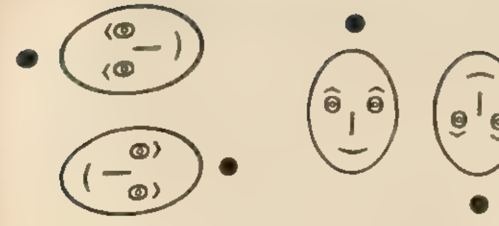

FIGURE 1. Examples of face–dot displays used for (a) horizontal conditions of Experiment I and (b) vertical conditions of Experiment II. (All 4 pictures require the response *yes* when presented with the word *above*, and *no* when presented with the word *below*.)

the word *below* refers to a negative pole on a dimension of verticality (Clark & Chase, 1972). Thus, the word *above* may be represented as + vert/ + polar and the word *below* as + vert/ − polar, indicating that these words are semantically represented as sharing values on a verticality feature, but as referring to positive and negative poles of the vertical dimension (Leech, 1969). Chase and Clark (1971) argued that the −polar case involves some addition to the sentence-encoding stage of the comparison.

The introduction of the notion that *below* is an inherently negative concept suggests a further line of theorizing which may be relevant to interpretation of the *above–below* asymmetry. Schaeffer and Wallace (1970) described a model for comparisons of word meanings in which semantic similarity, as determined by a preliminary holistic comparison of 2 word concepts, affects the thresholds of *same* and *different* counters used to test for equivalence of the 2 concepts with respect to some specified attribute. Semantic similarity tends to lower thresholds for *same* judgments and to raise thresholds for *different* judgments; conversely, semantic dissimilarity raises the threshold for *same* judgments, but lowers the threshold for *different* judgments. Seymour (1973) proposed that the inherent positivity or negativity of the concepts to be compared might have effects analogous to those of semantic similarity. Thus, if the representation of an *above* above word–picture display is inherently positive, as Clark argued, this display may result in a greater reduction in the threshold for a *yes* response than a *below*–below display. As a preliminary test of this assumption, Seymour instructed *S*s to report *no* to *above*–above and *below*–below displays, and *yes* for *above*–below and *below*–above displays. This reversal of the congruence-report mapping eliminated both the *above* below and the *true–false* effects. It was argued that this result was incompatible with the assumptions of the Chase and Clark (1971) model, but might arise if the advantage of *above*-above displays depended on the possibility of mapping the display onto a semantically affirmative report.

It seems possible, therefore, to identify 3 general theories about the nature of the asymmetry observed in verticality judgments. (*a*) A *perceptual* theory states that *S* scans the picture display from top to bottom, or attends initially to the upper region of the figure, so that encoding time is less for above pictures than for below pictures. This is the theory which was attacked by Chase and Clark (1971), although, as mentioned above, they restated an attentional variant of it in the discussion of their Experiment 4. (*b*) A *linguistic* theory states that the concepts *above* and *below* differ in semantic complexity, and that the marked term, *below*, requires more time at the word-encoding stage than the unmarked term, *above*. Pictures are encoded in the same abstract or propositional format as sentences, so that a comparable difference in encoding time is postulated for above vs. below pictures. (*c*) A *response availability* theory states that positive features in the semantic representation of the word–picture display tend to reduce the threshold for selection of a *yes* response. Responses to *above*–above displays are faster than responses to *below*–below displays because there is greater inherent positivity in the representation of *above*–above.

This article describes 2 experiments which were designed to discriminate among these 3 theories.

EXPERIMENT I

Experiment I aimed to distinguish between the perceptual and linguistic theories.

The *Ss* matched the words *above* or *below* against the location of a dot which was positioned relative to a horizontally oriented reference face. Figure 1(a) shows the face–dot configurations in which the dot was located above the face. In the below displays, the dot was located close to the chin of the face. Thus, the above and below locations might be to right or left of the display, depending on the position of the top of the face. This type of display eliminates any possible advantage for focusing attention on the upper part of the figure, and controls for tendencies to focus attention to the left or right. If the *above–below* asymmetry disappears under these conditions, it will follow that the effect is largely attributable to a distinction between the above and below locations, or spatial/perceptual factors. If the asymmetry persists, this will count as support for Clark's contention that *above* concepts may be established more rapidly than *below* concepts, but will also be compatible with the assumptions of the response availability theory.

Method

Subjects. Eight volunteers from final year classes at Dundee, Scotland, senior secondary schools served as unpaid *Ss*.

Apparatus. On each trial a warning tone was sounded for 500 msec. followed by a 1-sec. delay after which the word and picture displays were rear-projected onto a screen for 2 sec. The light sources of 2 projectors were obscured by a leaf shutter, which could be deflected by pulsing a galvanometer mounted on top of the projector. A Venner clock started when the projector shutters were opened, and stopped when *S*'s vocal *yes* or *no* response closed the relay of a voice key.

Displays. The words *above* and *below* were printed in lowercase Letraset (Univers 55) on cards and then photographed and mounted as slides. The pictures were faces similar to those shown in Figure 1, with a dot above the head or below the chin. The ellipse outline of the face was 5 cm. in length, and the center of the dot was 1 cm. from the circumference of the ellipse. These pictures were also photographed, and 2 slides were made for each picture, so that the face could be presented in horizontal orientation, with the top of the head to the left or right of *S*, and the dot located at the top of the head or at the chin. On each trial, *S* saw the word *above* or *below* displayed above 1 of the 4 face pictures. Under the conditions of the experiment, the visual angles subtended by the word and picture were 2° and 3°, respectively.

TABLE 1

MEAN RESPONSE LATENCIES (IN MSEC.) OF *yes* AND *no* REACTIONS TO *above* AND *below* DISPLAYS WHEN THE REFERENCE FACE WAS HORIZONTALLY ORIENTED: EXPERIMENT I

Head direction	*above*–above	*below*–below	*above*–below	*below*–above
Right				
M	976	1,055	1,122	1,114
SE_M	55	70	74	55
Left				
M	985	1,039	1,081	1,134
SE_M	63	77	78	91
M	981	1,047	1,102	1,124

Procedure. All *Ss* started with some practice in the use of the voice key and in classification of the displays. They were instructed that they should respond *yes* as rapidly as possible when the word display correctly specified the position of the dot relative to the face, and *no* when it did not. The main test session was organized as 3 blocks of 32 observations. Each of 8 word–picture combinations occurred 4 times per block in a random order independently determined for each *S* at each block. Error responses were discarded and replaced. Each 30–45-min. testing session was carried out in a quiet darkened room.

Results and Discussion

Error rates in this experiment were quite low, amounting to only 2.5% of all trials, and were not related in any consistent way to the main conditions of the experiment.

A summary of the latency data is given in Table 1, classified by word–picture combination (*above*–above, *below*–below, *above*–below, and *below*–above) and location of the dot (left or right). Each mean is based on 12 observations on each of 8 *Ss*. A preliminary analysis of variance established that the effects for dot locations were not significant, either for *yes* or for *no* responses, *F*s $(1, 7) < 1$ and 1.6, and that the interaction of this factor with effects for the words, *above* or *below*, also was not significant, $F\ (1, 7) < 1$.

The RTs were collapsed across dot position, and an analysis of the type employed by Chase and Clark (1971) was run to test the effects of response (*yes* vs. *no*) and word (*above* vs. *below*). This analysis indicated that *same* combinations were verified about 100 msec. faster than *different* combinations, $F\ (1, 7) = 59.89$, $p < .001$. Neither the *above–below* differ-

Summed negativity	2	4	5	5
Neutral components	2	2	2	2

ence of 44 msec., F (1, 7) = 4.14, nor the Response × Word interaction, F (1, 7) = 1.67, was significant. In a similar analysis, in which response and above vs. below pictures were factors, neither the pictures effect, F (1, 7) = 1.67, nor the Response × Pictures interaction, F (1, 7) = 4.14, was significant.

These results contrast with those obtained for vertically oriented displays by Seymour (1969) and Chase and Clark (1971). Both previous studies showed highly significant effects for *above* vs. *below* and for *same* vs. *different*. In the present experiment, there was a large *same–different* effect, but the *above–below* effect was not significant. Hence, if one adopts the assumptions about independence and additivity of component encoding and comparison stages stated by Chase and Clark (1971, 1972) and Clark and Chase (1972), an appropriate conclusion might be that the *above–below* effect is dependent on the vertical arrangement of the picture display, but that the *same–different* effect is independent of this factor. This conclusion is contrary to the predictions of the linguistic theory, which states that encoding time is shorter for *above* sentences and above locations than for *below* sentences and below locations. Use of a horizontal reference face might be expected to add a small constant to the duration of the picture-encoding stage. It should not, however, affect the difference in encoding time as between *above* and *below* sentences, or above and below pictures, which, in the theory, are supposed to reflect the time required to set up abstract propositional representations.

The main prediction of the perceptual theory appears to be that there should be no difference between the *same* displays, *above*–above and *below*–below, or between the *different* displays, *above*–below and *below*–above, although there may be an overall *same–different* effect. This would follow if the *above–below* effect depended on location of the critical dot in the upper region of the figure. In the case of *no* responses, the differences between *above* and *below* displays were not significant, F (1, 7) < 1. However, in the case of *yes* responses, the difference of 66 msec. between *above*–above and *below*–below was significant, F (1, 7) = 6.46, p <.05. The outcome for *no* responses is consistent with the perceptual theory, therefore, but the outcome for *yes* responses is not.

In order to consider the predictions of the response availability model, it is necessary to make a number of assumptions about the nature of the semantic representation of the word–picture display. A possible formulation has been outlined in Table 2. It has been assumed that the encoding of the display involves establishment of featural descriptions of (a) the word *above* or *below*, (b) the absolute location of the dot (left or right), (c) the absolute location of the top of the face (left or right), (d) the outcome of a comparison of dot location and face–top location, (e) a comparison of word polarity and match or mismatch of the dot and face–top locations, and (f) an indication of truth or falsity of the display. The form of the featural description for word meaning, and dot and face–top location, is based on semantic analyses of locatives proposed by Leech (1969). The

TABLE 3

Possible Semantic Representation of Normal and Inverted Face *above–below* Displays

Summed negativity	0	3	4	3	2	3	4	5

vertical dimension is characterized by the feature +vert, and the horizontal dimension by the feature −vert. The upper region of the vertical dimension is defined as positive and has the feature +polar. The lower region is negative and is assigned the feature −polar. Since the horizontal dimension is probably not bipolar in this sense, the directions left and right have been represented by the neutral features ← left and → right. The outcomes of the various comparison operations are represented by the features +match and −match.

It is assumed that as *S* encodes the display a featural representation of the type suggested in each column of Table 2 is constructed. The response to be made depends ultimately on inspection of the value for the +match or −match feature, which defines the outcome of the comparison of word polarity and dot/face–top congruity. This corresponds to the test for sameness or difference of value in relation to a specified attribute in the model of Schaeffer and Wallace (1970). It is further assumed that, as the semantic representation of the display is constructed, positive feature values tend to reduce the threshold for initiation of a *yes* response, whereas negative feature values will reduce the threshold for a *no* response.

The last 3 rows of Table 2 show the values obtained by making a simple count of positive, negative, and neutral features for the 4 displays. Summed positivity for an *above*–above display has a value of 5 vs. a value of 3 for a *below*–below display Hence, the reduction in threshold for the *yes* response is expected to be somewhat greater for *above*–above than for *below*–below, and this might give rise to the small but significant difference in RT that was observed. In the case of *no* responses, summed negativity has a value of 5 for both *above*–below and *below*–above displays. Thus, these 2 displays will be expected to reduce the threshold for a *no* response by an equivalent amount, and no difference in RT is expected.

Experiment II

Experiment II was carried out with the aim of determining the effects on the *above–below* and *true–false* differences of inversion of the reference face. The words *above* and *below* were matched against the location of a dot relative to a reference face which might be normally oriented, or inverted, as shown in Figure 1(b). The normal orientation of the face corresponds to the condition tested in the studies by Seymour (1969) and Chase and Clark (1971), and may be expected to reproduce the significant *above–below* and *same–different* effects obtained in those studies. However, the 3 theoretical positions discussed earlier lead to different predictions for the case where the reference face is inverted.

If, as is implied by the perceptual theory, the *above–below* asymmetry depends on a tendency to focus attention on the top of the figure or to scan the figure in a top–down direction, inversion of the face should

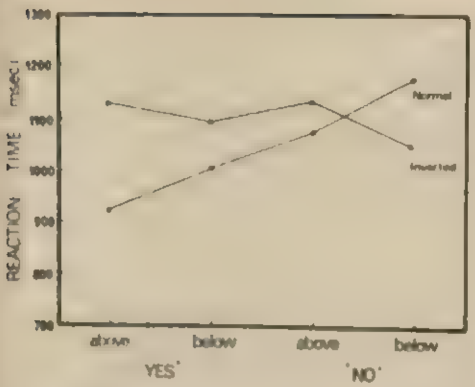

FIGURE 2. Summary of mean reaction times (in msec.) for classification of vertical face displays (Experiment II). (The means are for *yes* and *no* responses to *above* and *below* displays when the face might be normally oriented or inverted.)

result in a symmetric reversal of the *above–below* effect. This assumes that *S* may take some time to note the inversion of the face, but that, once this has occurred, he will encounter the evidence critical for verification of the display sooner for a *below*–below combination than for an *above*–above combination. Since these effects are arising at the stage of picture encoding, the *same–different* effect should not be altered.

An assumption of the linguistic theory is that an abstract representation of "X above Y" may be set up more rapidly than a representation of "X below Y," for both sentences and pictures. If sentence encoding and picture encoding are genuinely independent mental operations, inversion of the reference face will not alter the difference in encoding time as between the words *above* and *below*. The effect of inversion should be on the duration of the picture-encoding stage, and should also be a constant increment which will leave the difference in encoding time for *above* vs. *below* pictures unaltered. Further, if the encoding stages are independent of the comparison stage, inversion of the face should not influence the magnitude of the *same–different* effect. In general, therefore, the linguistic theory predicts a constant increment in RT when the face is inverted, but no change in the basic *above–below* and *true–false* effects.

The predictions of the response availability model must again depend on an assessment of the balance of positive and negative components in the semantic representation of the displays. Table 3 gives the outcome of an analysis which is similar in form to that proposed for the horizontal faces. Word meaning, dot location, and face orientation are represented by a +vert feature and a +polar or −polar feature, and the outcomes of comparisons of dot location and face–top location, or word polarity and congruence of dot and face–top, by +match or −match features. The last 2 rows of the table show the values for summed positivity and summed negativity obtained for each display. For normal orientation of the face, there are 9 positive components in the representation of an *above*–above display, but only 6 in the representation of a *below*–below display. However, when the face is inverted, the ratio of positive components becomes 7:6. The prediction of the response availability model for *yes* responses, therefore, is that there will be a significant difference between *above*–above and *below*–below displays when the face is normal, but that this difference will be much attenuated when the face is inverted. In the case of *no* responses, the ratio of negative components is 4:3 in favor of *above*–below for normal orientation of the fact, but 5:4 in favor of *below*–above when the face is inverted. The best prediction, therefore, is that *above*–below will be classified faster than *below*–above when the face is normal, but that the direction of this difference will be reversed when the face is inverted.

Method

Subjects. Eight volunteers, all University of Dundee students, served as unpaid *Ss*.

Apparatus and displays. These were identical to Experiment I except that the faces were now displayed in a normal or inverted orientation, and the word display appeared to the left of the picture on each trial.

Procedure. The procedure was similar to that followed in Experiment I. After some preliminary practice, each *S* recorded a total of 96 observations in which each of 8 word–picture combinations occurred 12 times in random orders independently determined for each *S*. Error responses were discarded and replaced.

Results and Discussion

Error rates were again low in this experiment, being limited to 2.8% of all trials.

Figure 2 gives a summary of the latency data for the 4 word–picture combinations and for normal or inverted orientation of the reference face. A preliminary analysis was carried out to assess the effects of inversion of the face in relation to differences among the word–picture combinations. This analysis indicated that inverted face displays were classified about 58 msec. slower than normal face displays, $F\ (1, 7) = 71.73$, $p < .001$, and also that there were significant differences among the word-picture combinations, $F\ (3, 21) = 10.39$, $p < .001$. The Orientation × Displays interaction was also significant, $F\ (3, 21) = 20.50$, $p < .001$.

The interaction between face orientation and differences among word–picture displays appears contrary to the predictions of the linguistic model of Chase and Clark (1971). If inversion of the face added a constant to the duration of the picture-encoding stage, and picture encoding, word encoding, and comparison were truly independent operations, the effects for displays and face orientation would be independent. As it is, the results for the normal face appear similar to those obtained in the previous studies, in that they show quite large *above–below* and *true–false* differences, whereas these differences are absent, or in the opposite direction, when the face is inverted.

As a check on these conclusions, an analysis was carried out on the data for the normal face condition in which response (*yes* vs. *no*) and word (*above* vs. *below*) were factors. The differences of 163 msec. between the means for *yes* and *no*, and of 91 msec. between *above* and *below* displays, were significant, with $Fs\ (1, 7) = 35.74$, $p < .001$, in both cases, although the Response × Word interaction was not significant, $F\ (1, 7) < 1$. A similar analysis of RTs for the inverted face displays failed to show a significant response effect, $F\ (1, 7) < 1$. Displays with the word *below* were classified 60 msec. faster than displays with the word *above*, and this reversal of the usual effect was significant, $F\ (1, 7) = 6.93$, $p < .05$. The Response × Word interaction was not significant.

In the case of *yes* responses, inversion of the face resulted in a delay of response of about 200 msec. for *above*–above combinations, and about 90 msec. for *below*–below combinations. The difference between the 2 *same* displays was significant when the face was normally oriented, $F\ (1, 7) = 13.41$, $p < .025$, but not when the face was inverted, $F\ (1, 7) = 1.46$. Thus, for congruent combinations, inversion of the face resulted in an overall delay in RT, and also in elimination of the *above–below* difference. This outcome appears consistent with the predictions of the response availability theory but not those of the linguistic or perceptual theories. The linguistic theory predicts maintenance of an *above–below* difference when the face is inverted, whereas the perceptual theory predicts a reversal of this difference. The count of positive features shown in Table 3 indicates that the *above–below* effect should be attenuated when the face is inverted, and it was this result that was obtained.

Further analyses of *no* response times indicated that inverted face displays were classified 33 msec. faster than normal face displays, but that this difference was not significant, $F\ (1, 7) = 3.13$. The effect for words (*above* vs. *below*) also was not significant, but there was a significant Orientation × Words interaction, $F\ (1, 7) = 24.67$, $p < .01$. The absence of an effect for face orientation and the occurrence of the interaction appear counter to the predictions derived from the linguistic theory. The result is also in the wrong direction for the perceptual theory, since displays having the dot in the lower region of the figure were classified significantly faster than displays having the dot in the upper region, $F\ (1, 7) = 24.67$, $p < .01$. However, the interaction is consistent with the predictions of the response availability model. Summed negativity has a value of 4 for *above*–below combinations for both normal and inverted orientations of the face. When the face is normal, the representation of the *below*–above display contains only 3

negative components. Thus, under this condition, *no* responses should be faster to *above*–below displays than to *below*–above displays, and this is indeed the case, $F\ (1, 7) = 20.93$, $p < .01$. When the face is inverted, the sum of negative components in the *below*–above representation increases to 5. This increment in negativity is expected to lower the threshold for selection of a *no* response. The data indicate that, under this condition, *below*–above displays were classified significantly faster than *above*–below displays, $F\ (1, 7) = 12.63$, $p < .025$.

A further point of difficulty for both the perceptual and the linguistic theory is raised by the failure to obtain a *true–false* effect under the inverted face condition. If, as both theories imply, inversion of the face has its main effect on the duration of a picture-encoding stage, and this stage is independent of a comparison stage, there should be no effect on the magnitude of the *true–false* difference. In the model of Chase and Clark (1972), and Clark and Chase (1972), the *true–false* effect is defined as the time required to alter a "truth index" from "true" to "false." If this is correct, a *true–false* effect would be obtained in both the normal and the inverted face conditions. Thus, the absence of an effect in the present situation counts as evidence against Chase and Clark's (1971, 1972) assumptions about the independence and additivity of the encoding and comparison stages. The response availability model is sufficiently flexible to accommodate variations in the size of the *true–false* effect. For example, presence of a negative feature for face orientation might raise thresholds for *yes* responses and lower thresholds for *no* responses, thus overriding a general bias in favor of *yes* responses.

General Discussion

The analyses of these 2 experiments appear sufficient to eliminate the perceptual theory of Seymour (1969) as an explanation of the *above–below* asymmetry observed in word–picture comparison tasks. The theory must have difficulty in accommodating (*a*) the difference between *above*–above and *below*–below observed for horizontal face displays, (*b*) the absence of a difference between these 2 displays observed when the [illegible] inverted, (*c*) disappearance of the [illegible] effect when the face was inverted, and [illegible] tendency is Experiment II for *no* responses to occur faster to displays having [illegible] lower region than to displays having the dot in the upper region.

The experimental results also appear sufficient to disconfirm Chase and Clark's (1971 assumption that the RT in this type of comparison task is the sum of the [illegible] independent and successive w[illegible] picture encoding, comparison and res[illegible] stages, which differ in duration for *above* v[illegible] *below* concepts and for *true* vs. *false* displays If word encoding and picture encoding were truly independent operations, an alteration in the orientation of the reference face would affect only the duration of the picture-encoding stage. Further, if the comparison depended on establishment of abstract assertions of relative location, and above assertions were established quicker than below assertions, picture encoding should be faster for above displays than for below displays even when the face is inverted or rotated to the horizontal. The difference in time to encode the words *above* and *below* should also remain unaffected, as should the comparison time difference between *true* and *false* displays. The data are inconsistent with this position in the foll[illegible] respects: (*a*) The overall effects [illegible] (*above* vs. *below*) and picture locati[illegible] vs. below) were not significant when the [illegible] was horizontally oriented or when [illegible] inverted. (*b*) The *true–false* effe[illegible] nated when the face was invert[illegible] version of the face did not result in [illegible]verall delay of reaction for *no* responses in Experiment II, but did result in a reversal in the direction of the difference between *above*–below and *below*–above combinations.

It has been argued that the obtained results are consistent with a response availability model of the type which has been described. The main assumption of the model is that variations in RT in the sentence–picture comparison task reflect momentary adjustments in thresholds for selection of *yes* or *no* responses which occur as the encoding the display proceeds. Positive features in the representations of word and picture meaning, or positive outcomes of matching operations, tend to lower the threshold for a *yes* response. It is a facilitation effect of this sort that underlies

the *above–below* difference, rather than an absolute inequality in encoding time. This explanation may be extended to other pairs which involve an unmarked/marked, or +polar vs. −polar distinction, such as *large* vs. *small* (Seymour, 1971). A formulation of this type is sufficiently flexible to accommodate cases where the effect does not occur. For example, both the *above–below* and the *large–small* effects may be eliminated by instructing *S*s to report *no* to *same* displays, and *yes* to *different* displays. In the present experiments, an alteration in the orientation of the reference shape was sufficient to attenuate or eliminate the *above–below* effect. It was argued that this might occur if a shift from normal vertical orientation of the reference face had the effect of introducing negative components into the semantic representation of the picture. As shown in Tables 2 and 3, this tends to decrease the difference in summed positivity scores as between the *above*–above and *below*–below combinations, and this in turn will reduce the difference in *yes* response times.

An important feature of the response availability model is that it predicts that facilitation of *no* responses may occur when the number of negative components in the representation of the display is increased. The summed negativity scores in Tables 2 and 3 correctly predict (*a*) the absence of a difference between *above*–below and *below*–above displays when the face is horizontal, (*b*) similar RTs for *above*–below for normal and inverted face displays, (*c*) faster times for *below*–above when the face is inverted than when it is normally oriented, and (*d*) a reversal in the direction of the difference between *above*–below and *below*–above for normal vs. inverted face displays. The model can also accommodate interactions of display characteristics with the size of the *yes–no* difference if negativity in the semantic representation tends to equalize the thresholds for the *yes* and *no* responses.

The main contention of this article, therefore, is that RTs obtained in a simple word–picture comparison task may be quite well represented in terms of effects of semantic positivity/negativity on thresholds for *yes* and *no* responses. Some question arises about the generality of these conclusions, and in particular whether the difficulty encountered by the additive stages model in relation to the present, relatively simple, experimental situation necessarily implies a weakness in the more complex situations examined by Chase and Clark (1972) and Clark and Chase (1972). Krueger (1972) has presented evidence that the encoding and comparison stages are not additive in their effects on RT in the sentence–picture comparison task, in that effects attributable to sentence form (affirmative vs. negative) interact with effects supposedly arising during encoding (axis match effect). In general, the consequences of a negative in the sentence should be quite similar to those of inverting the face (negating the picture) in Experiment II of the present study, and should tend to eliminate or reverse the *true–false* effect. Thus, the Affirmative–Negative × True–False interaction obtained by Clark and Chase (1972) and other investigators may be handled by the response availability model, if it is assumed that a negative in the sentence causes a general rise in both response thresholds, and also tends to lower the *no* threshold relative to the *yes* threshold.

CONTEXT AND FREQUENCY EFFECTS IN THE GE[illegible]TION OF A HUMAN VOLUNTARY RESPONS[illegible]

JOHN A. HÉBERT,[1] MARSHA BULLOCK, LYNN LEVITT, KIM GR[illegible]
AND FRANK D. McGUIRK

Colorado State University

Three studies investigated the effect of presenting a given tes[illegible] more frequently than the other test stimuli on generalization. [illegible] training on a single stimulus, either 100, 150, or 200 gm., *Ss* wer[illegible] identify the stimulus in a test series of 5 weights, ranging in value 10[illegible] in 25-gm. steps. Systematically overrepresenting each of the 5 t[illegible] produced an ordered set of generalization gradients. A tenden[illegible] generalization responses to shift toward the overrepresented test stim[illegible] observed. The data were interpreted in terms of adaptation level t[illegible] Direct evidence was found for the link between generalization resp[illegible] adaptation level operationally defined by the category-rating method.

In human voluntary stimulus generalization, the context in which the original training stimulus (S+) is placed in testing has been shown to greatly alter the shape of the gradient of stimulus generalization. In an asymmetrical context (e.g., S+ is either the largest or smallest of the test values), *Ss* tend to choose central values of the test range as the original training stimulus more often than the S+ value itself (Thomas & Jones, 1962). This central-tendency effect has since been found with the following stimulus dimensions: size–area (Helson & Avant, 1967), weight (Hébert, Origlio, & McGuirk, 1972; Hébert & Capehart, 1969), brightness (Thomas, Svinicki, & Vogt, 1973), and line angle (Giurintano, 1972). However, Thomas and Jones, using hue as a dimension, also found that *Ss* respond accurately to S+ as the original training stimulus if S+ is placed symmetrically in the middle of the test values. That *Ss* tend to respond to central values of the test range *regardless* of the position of S+ in that test range was confirmed by Helson and Avant.

Related to this context effect is the finding that presenting S+ more frequently than the other test stimuli negates the central-tendency effect in an asymmetrical test context (Hébert & Capehart, 1969; Hébert et al., 1972). In both studi[illegible] following training on single weight [illegible] group of *Ss* was tested with an "overrepresentation" proced[illegible] [illegible]ich S+ was presented 5 times m[illegible]quently than other test stimuli. Another group was given an "equal-presentation" procedure in which S+ was presented equally as often as the other test stimuli. Since S+ was the smallest value in the test series, creating an asymmetrical context, a central-tendency effect would be expected. However, the overrepresentation-procedure group did not tend to choose central values as S+, as did the equal-presentation group, but rather, correctly chose the S+ value more often than any other test stimulus, yielding a downward, linear gradi[illegible] Thus, a strong frequenc[illegible] with a context effect. Giurintano (1972) has also demonstrated [illegible]nomenon with a line angle dimensi[illegible]

Capehart, Tempone, and Hébert (1969) interpreted these data in terms of an adaptation level (AL) approach to a stimulus generalization. According to AL theory, when *S* is presented with a single stimulus value in training, a training AL is established at that value on a subjective dimension. What *S* learns is not "stimulus of value *x* is correct" but "the stimulus whose value corresponds to AL is correct." Thus, if in testing AL shifts away from S+ for some reason such as an asymmetrical context, then a concomitant shift in *S*'s

[1] Requests for reprints should be sent to John A. Hébert, Department of Psychology, Colorado State University, Fort Collins, Colorado 80521.

judgment of which stimulus is S+ will be observed. The AL by which *S* makes a judgment can be represented as a weighted average of the training and test ALs:

$$\text{AL} = w_1\text{AL}_{\text{train}} + w_2\text{AL}_{\text{test}}, \qquad [1]$$

where w_1 and w_2 are subjective weights which sum to 1 and reflect the relative contributions of training and testing to the prevailing AL. With this model, varying the *amount* of training or of testing would alter the values of the subjective weights and thus result in different prevailing ALs. Similarly, the value of the training AL can be manipulated by choosing different values for S+, while the value of the test AL can be manipulated by choosing different test stimuli. In addition, the value of the test AL can be altered by manipulating the frequency of presentation of test stimuli. For example, when S+ is overrepresented in testing, greater weight is given to it in averaging the stimuli to obtain AL (Capehart et al., 1969; Helson, 1964). The greater weight given the overrepresented stimulus biases or "pulls" AL toward that value.

However, the frequencies of stimuli other than S+ can also be manipulated. Suppose, for example, that S+ is the smallest of 5 test stimuli, and that the stimulus value *most distant* from S+, say S_5, is presented with much greater frequency than the other 4 test stimuli, including S+. Under these circumstances, S_5 would have greater weight, pulling AL towards it, thus producing a larger discrepancy between training and test ALs. This would produce the greatest amount of shift in the gradient, possibly *beyond* the center of the test values. A design that systematically manipulates the frequencies of presentation of each test stimulus independently could provide a more exacting test of the AL approach. An ordered set of gradients should be obtained if the model is at least correct in an ordinal sense.

Anderson's (1971) work in integration theory and its relation to AL (Anderson, 1973) also suggests a rigorous test of the averaging hypothesis of Equation 1. A factorial design in which both the training and test ALs are manipulated should yield test data which must meet the key prediction of a simple averaging model: A graphical representation of the interaction between training and testing manipulation should yield parallel curves. That is, the Training × Testing interaction should be "zero in principle and nonsignificant in practice [Anderson, 1970, p. 155]." What is needed to make this test of the averaging model is a response measure directly related to the prevailing AL.

The present experiments were designed to test the effects of systematically manipulating the frequencies of presentation of the test stimuli in both symmetrical and asymmetrical test contexts. In addition, an experiment to tie *S*'s responses directly to Helson's (1947, 1964) operationally defined AL concept was conducted.

Method

Experiments I and II were designed to test the effect of manipulating test stimulus frequencies following training on either the lightest or heaviest of the test stimuli (Experiment I) or following training on the intermediate value of the test stimuli (Experiment II).

Subjects and apparatus. A total of 120 students served as *S*s in Experiment I; 60 students served as *S*s in Experiment II. The *S*s in both experiments were participating as a course requirement. The stimuli consisted of a set of 5 weights ranging in value 100–200 mg. in 25-gm. steps. The weights were made from aluminum cans 10.8 cm. tall and 5.5 cm. diameter, and were filled with wax and shot and painted to appear identical. When the blindfolded *S* lifted a given weight with the preferred hand, a microswitch was released which started a timer. When *S* reached a decision (*same* or *different*), he pressed 1 of 2 response keys with the index finger of his free hand, which rested above and between 2 closely spaced response keys, labeled same and different. The pressing of 1 of the 2 keys stopped the timer and activated a response light, and *E* then recorded choice and latency of response.

Procedure. The *S*s were told that they were participating in a weight perception experiment. In Experiment I, they were instructed to lift the training weight or S+ (either 100 or 200 gm.) 5 times and to remember it because they were to identify it in a test series of weights immediately following training. They were told to press a *same* key if a test stimulus was the same as S+, or to press a *different* key if they felt it was different (either heavier or lighter). In addition, *S*s were asked to respond "as quickly and accurately as possible." Following instructions, all *S*s were

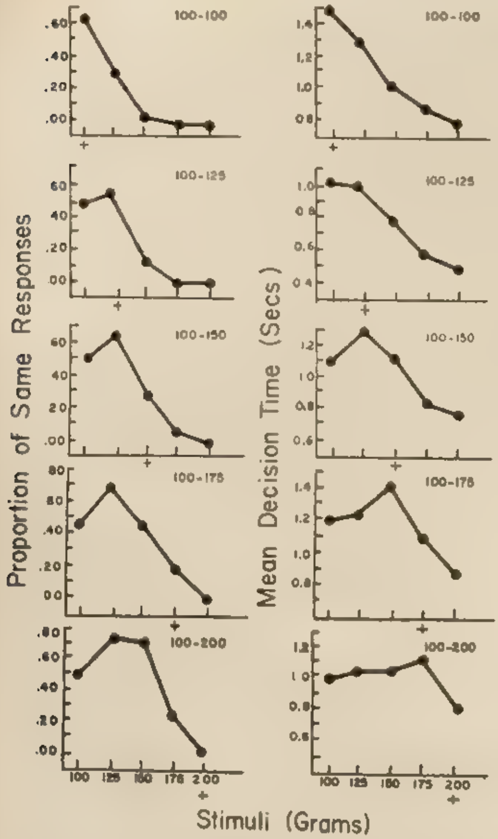

FIGURE 1. Generalization gradients of *same* responses and decision time for the 100-gm. training group.

blindfolded for the rest of the session. The training procedure for Experiment II, conducted after the completion of Experiment I, differed in only one respect, namely, *S*s were trained on 150 gm., the intermediate value of the test series. Testing procedures were identical in both experiments.

Following training, which consisted of lifting S+ 5 times in a slow, paced fashion, test trials were immediately begun. A test trial consisted of *S*'s grasping the weight from the top with 4 fingers and a thumb, lifting the weight up with elbow resting on table, making the response, bringing the weight down, and releasing it. Shaking or swinging the weight was not permitted.

In Experiment I, half of the *S*s were trained on 100 gm. and half on 200 gm. Following this, *S*s in both groups were assigned randomly to 1 of 6 test groups, 10 *S*s per group, yielding a 2 × 6 factorial design. The 6 test groups for both the 100- and 200-gm. training groups consisted of a control group in which the 5 test stimuli were presented equally often (5 times each) and 5 other groups which differed in terms of which test stimulus was overrepresented. There were 25 presentations of the overrepresented stim[illegible] [illegible]presentations of each of the other stimuli. [illegible] procedure was identical in Experiment I[illegible] [illegible] groups of 10 *S*s each with 1 group an [illegible]presentation control group and the remaining [illegible] differing [illegible] of which stimulus was [illegible]represented. For discussion purposes, groups [illegible] identified by designating first the traini[illegible] (100, 150, and 200 gm.) and then the st[illegible] represented for that group. For exam[illegible] 100-175 was trained on 100 gm. and in [illegible] presented 5 times more frequently tha[illegible] stimuli. The equal-presentation control [illegible] labeled 100-E and 200-E for Experiment I, [illegible] for Experiment II.

Stimuli were presented in a [illegible]mized order within a block of 9 trials, wit[illegible] the overrepresented sti[illegible] 3 times in succession. A block of 9 trials consisted of 5 presentations of the overrepresented stimul[illegible] intermixed with 1 presen[illegible] of the other remaining stimuli. In [illegible] of trials, a total of 45 trial[illegible] the 100-E and 200-E co[illegible] I and the 150-E group f[illegible] were given 5 blocks of 5 [illegible]

Design and analysis. Th[illegible] Experiment I were analyzed separately fr[illegible] those of Experiment II. Analysis for Experiment I involved a 2 × 5 × 5 factorial design with repeated measures, with 2 training conditions and the 5 overrepresentation groups as between-subjects variables, and the 5 test stimuli as the repeated variable. Two dependent measures were analyzed by this design, proportion of *same* responses and response latency. The proportion of *same* responses to all response[illegible] by a given *S* across blocks of trials served as [illegible] main dependent measure. Latency, defined [illegible] time from lift to key press, was averaged [illegible] trials for each stimulus and *S*. These late[illegible] were calculated on the basis of *both same* and *different* responses to a given stimul[illegible] Data from the 100-E and 200-E control gr[illegible] separately and compared [illegible] group of Experiment II. [illegible] ment II involved a 5 × 5 [illegible] with the 5 overrepresentation grou[illegible] test stimuli as a repeated variable.

RESULTS AND DISCUSSION

The generalization gradients for each of the 10 experimental groups are depicted in Figures 1 and 2 for the 100- and 200-gm. training groups, respectively. The left-hand columns of both figures depict gradients of *same* responses for each group, while the right-hand columns represent the latency data for the same groups. Inspection of the choice gradients in the left-hand columns of Figures 1 and 2 indicates

a systematically increasing tendency to choose stimuli farther from S+ as the overrepresented stimulus becomes farther from S+, as predicted from the AL model. Statistically, this is represented by a significant Test Procedure × Stimuli interaction, F (16, 360) = 5.13, $p < .001$. However, the amount of shift appears greater for the 200-gm. training groups, resulting in a significant Training × Test Procedure × Stimuli interaction, F (16, 360) = 4.31, $p < .001$. The most dramatic shift occurred with Group 200–100, whose data are presented in the bottom left-hand panel of Figure 2. This group shifted *past* the center (150 gm.) to some point between 100 and 125 gm. In contrast, Group 100–200, the counterpart of Group 200–100, failed to shift even quite to the center (see lower left-hand panel of Figure 1), if shift is defined by the modal response value or peak. This asymmetry may reflect the fact that the *perceived* midpoint of these stimulus values is closer to 125 gm. than to 150 gm., the arithmetic midpoint, when perceived midpoint is defined by AL. The AL of this test series is calculated to be approximately 128 gm. according to Helson's (1947, 1964) formula for lifted weights, and this value is confirmed by category-rating data from our laboratory. The notion of "central-tendency effect" (Thomas & Jones, 1962) might best be conceptualized as a tendency to respond to the psychological center, not the physical center.

Inspection of Figures 1 and 2 indicates a correspondence between choice and latency data. The stimuli most often associated with *same* responses are also associated with the longer latencies than those of stimuli rarely chosen *same*, though this correspondence is far from exact. Capehart et al. (1969) offered the explanation that stimuli close to AL are less "distinctive" than those far from AL, and therefore, take longer to respond to than the more "distinctive" stimuli far from AL. Since *same* responses are associated with AL, then *same* responses take longer.

The gradients of *same* responses of the 5 experimental groups from Experiment II

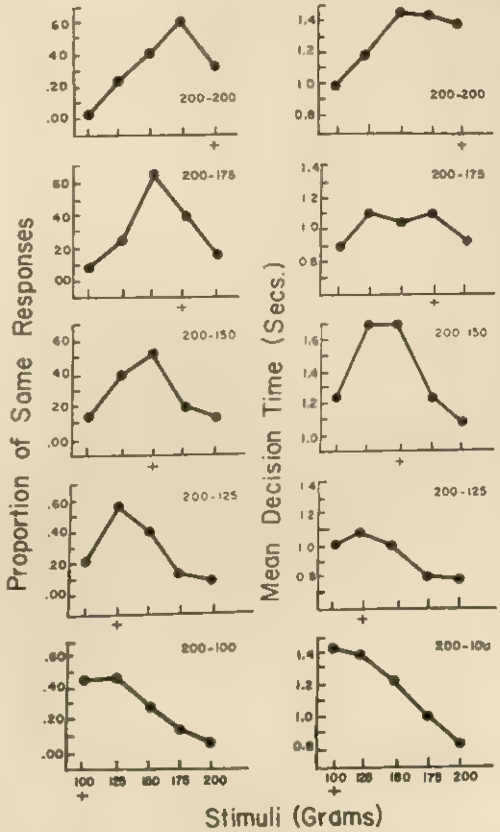

FIGURE 2. Generalization gradients of *same* responses and decision time for the 200-gm. training group.

are depicted in Figure 3A. It is clear from the inspection of these gradients that the same systematic effects of the frequency manipulation occurred here as in Experiment I, resulting in a significant Test Procedure × Stimuli interaction, F (16, 180) = 3.56, $p < .001$. The most notable aspect of Figure 3A is the asymmetry: The modal response value is 125 gm., not 150 gm., and the 100-gm. stimulus receives many more responses than its counterpart 200 gm. This again may be due to the fact that perceived midpoint of this series (defined by AL) is close to the 125-gm. stimulus, not 150 gm. Figure 3B depicts the gradients of the 100-E, 150-E, and 200-E control groups from both experiments, and again, the tendency to a shift in response toward the 125-gm. stimuli is apparent. The term *central tendency* should

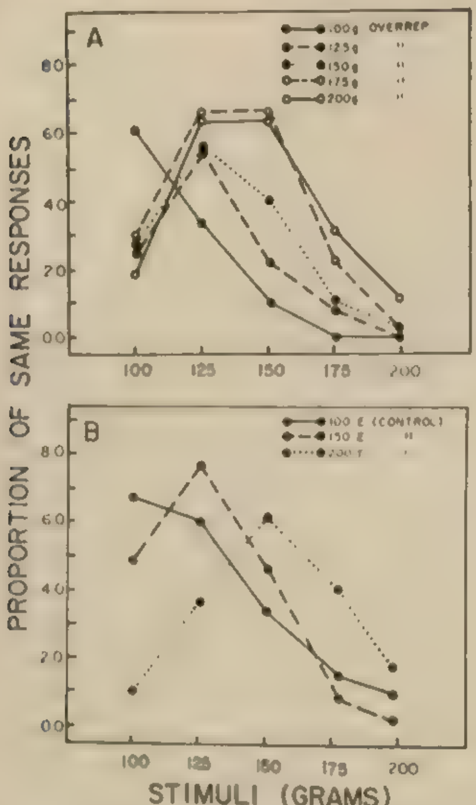

FIGURE 3. Generalization gradients for the experimental groups trained on the 150-gm. weight are plotted in the upper panel; generalization gradients for the equal-presentation control groups for Experiments I and II are plotted in the lower panel.

be used with caution since the 150-E group shifted *away* from the center of the series, although one could say *toward* AL, the psychological center. Note that the 100-E group did not actually peak at 125 gm., as in the Hébert and Capehart (1969) study, but at 100 gm. However, compared to the 100-100 group, there was a much greater tendency to respond to central values. An analysis comparing just these 2 groups still yields a significant Test Procedure × Stimuli interaction, F (4, 72) = 3.22, $p < .05$.

While the above data are consistent with the AL approach, a rigorous test of the model as expressed in Equation 1 is also possible. Normally, AL is measured by means of a category-rating method (Helson, 1947), but in this situation no ratings were taken. Capehart et al. (1969) proposed that the modal or peak response value is closest to AL in generalization experiments, and as such, is a crude indicator of AL. Unfortunately, this measure ignores responses to all other stimuli, and is, therefore, biased. A better index is the *mean response value* (Thomas, 1962) which takes into account responses to all stimuli by weighting each stimulus value by the frequency with which it was called *same*. The mean response value for each S in the 15 experimental groups in Experiments I and II was calculated and analyzed by means of a 3 × 5 completely randomized factorial design, with 3 training conditions (100, 150, and 200 gm.) and 5 test procedures (overrepresentation of 100 through 200 gm.). In terms of the additive model of Equation 1, 3 training ALs are factorially combined with 5 test ALs, and, further, a plot of the curves of these groups should be parallel, or noninteractive. The Training × Test Procedure interaction depicted in Figure 4 was not statistically significant, F (8, 135) = .65, $p > .05$, indicating that no meaningful interaction is present. However, Anderson (1973) has indicated that nonparallelism should be present in the form of a bilinear interaction. Since

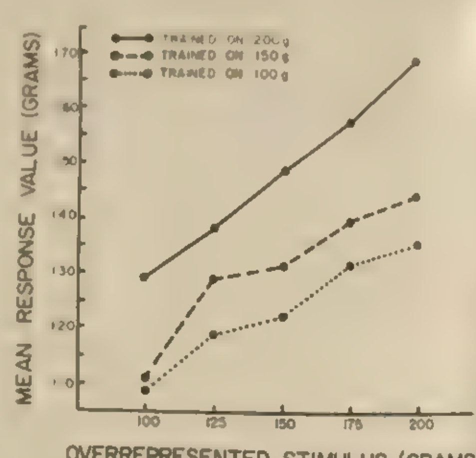

FIGURE 4. The nonsignificant Training × Test Procedure interaction for the 15 independent groups from Experiments I and II.

this interaction is concentrated in only 1 degree of freedom, a specific bilinear F test was made, but no significant interaction was found, $F\ (1,\ 135) = 2.27$, $p > .05$. Thus, the additive model of Equation 1 is not disconfirmed and remains a tenable hypothesis.

The question still remains whether the concept of AL as used in this study is substantially the same as the concept as operationally defined by Helson (1947, 1964); neither is there any direct evidence that *S*s were actually linking *same* responses to AL. A third experiment was conducted to answer these questions. Nine introductory psychology students served as *S*s. Training and testing of these students was identical to the 150-E control group. That is, *S*s were asked to heft the 150-gm. training weight 5 times, and then were required to identify S+ in a subsequent test series of 5 presentations each of the 5 test stimuli. However, the testing procedure differed in one important respect: Following each *same* or *different* response each *S* was asked to rate the weight just lifted on a 7-point category-rating scale (1 = very light, 2 = light, 3 = fairly light, 4 = neither light nor heavy, 5 = fairly heavy, 6 = heavy, 7 = very heavy). The 150-gm. training stimulus was not identified at any point on the rating scale by *E*, and no instructions to do so were given to *S*.

With this rating procedure, the stimulus which is closest to an average 4 rating can be assumed to be closest to AL, which would be operationally equivalent to a stimulus rated exactly 4. Figure 5 depicts the patterns of choice and latency of response for this third experiment. Inspection of the gradient of *same* responses (solid line shows that 125 gm. elicited the greatest proportion of *same* responses, not the 150-gm. S+). This is in close agreement with the gradient from Group 150-E shown in Figure 3B. As predicted, the 125-gm. stimulus also had the mean rating closest to 4.00 (100 gm. = 2.62, 125 gm. = 3.87, 150 gm. = 4.51, 175 gm. = 5.40, and 200 gm. = 6.20). The most compelling evidence that AL and *same* responses

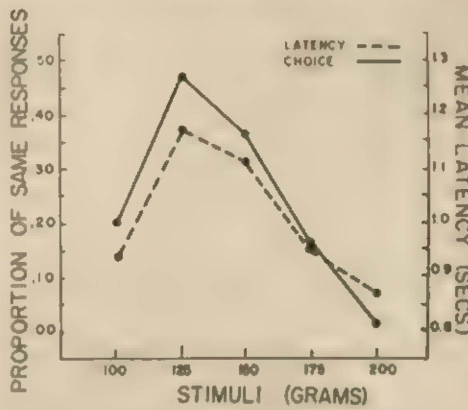

FIGURE 5. The latency and choice gradients of generalization for Experiment III.

are linked is the finding that 50 of the 54 *same* responses in this study were to stimuli which were subsequently rated 4. Additionally, none of the *different* responses were given a 4 rating.

These 3 studies taken together cast doubt on the assumption that physical similarity is the primary basis of stimulus generalization of voluntary responses in human *S*s. The powerful effects of frequency and context must be accounted for in any theory of voluntary stimulus generalization. The Capehart et al. (1969) theory of stimulus equivalence provides such an account, and the data in these studies offer strong support for the theory. As a final note, the reader should be reminded of the possibility of interpreting these data with Parducci's (1965) range-frequency model. Since both the AL and range-frequency approaches have generally the same qualitative predictions, range-frequency theory, with additional assumptions relating to a learning context (e.g., What is learned?), may be useful for the interpretation of these data.

RELATIONSHIPS AMONG HIGHER ORDER ORGANIZATIONAL MEASURES AND FREE RECALL[1]

JAMES W. PELLEGRINO[2] AND WILLIAM F. BATTIG

University of Colorado

Higher order subjective organization units were measured in categorical and unrelated lists under fixed and random presentation schedules. Such units occurred frequently and also varied in sequential consistency across recalls thereby demonstrating the inadequacy of pair-wise sequential indices for measuring total organization. Further data confirmed the necessity for examining such units since, when included as additional predictors, they accounted for 96% of the between-groups recall variance. Several other organization measures indicated interactive relationships between organizational processes and changes in such relationships with practice which may partially explain inconsistencies in the organization-recall literature. Additionally, the present organizational data raise questions about the adequacy of current theories of storage and retrieval processes in free recall.

Recent research in free recall has focused on the role of organizational processes in memory and questions concerning the storage and retrieval of information as related to such processes (e.g., Postman, 1972; Slamecka, 1968). Postman has noted 2 major current problems related to the study of organizational processes in free recall.

The first problem concerns the adequacy of certain organizational measures as valid indices of the total organization that has occurred at any point in learning, particularly with respect to measures of subjective organization (SO). The 2 major indices of SO—the intertrial repetition measure (Bousfield & Bousfield, 1966) and the SO measure (Tulving, 1962)—have been criticized as having very serious shortcomings both in the size of the sequential units that are examined and the strict sequential criteria that are employed. Shuell (1969) and others (e.g., Postman, 1972) maintain that such simple pair-wise sequential indices would seriously underestimate the actual organization that occurred if *S*s formed units containing more than 2 items with free-varying internal sequential constraints, i.e., the items within a unit always appear together but not necessarily in the exact same sequential order each time. Specifically, a unit of Size 5 could be randomly reproduced 5! possible ways which yield an average of only 1.6 pair-wise repetition as compared to a maximum of 4. Empirical justification for such criticism of the current measures therefore requires demonstrating (*a*) the existence of such higher order units and (*b*) that such units have internal sequential variability across successive recalls.

Pellegrino (1971) has presented a technique for measuring organization which is capable of dealing with both issues. Under this procedure, the degree of sequential consistency can be examined for units of any size rather than being limited only to units of Size 2. This technique also permits measurement of organization based on any of the following 3 different sequential criteria: (*a*) *unidirectional*, requiring exact reproduction of the sequen-

tial order, as characterizes most previous measures; (*b*) *bidirectional*, counting also a mirror-image reversal as an organizational unit; and (*c*) *unordered*, requiring only that the items be recalled together in any sequential order. For example, if Items A, B, and C were recalled in that order on Trial t, on Trial $t+1$ only A–B–C would represent a unidirectional unit, either A–B–C or C–B–A would be bidirectional units, whereas any of the 3! possible orderings of these 3 items would constitute unordered units. In the present measure the actual number of repetitions of each type is separately determined for Unit Sizes 2–5 and compared to an appropriate chance expected value. The actual chance deviation (observed–expected) is divided by the maximum possible deviation (maximum–expected) to provide a ratio organization score (adjusted ratio clustering, ARC′) whereby 0 represents chance and 1.0 perfect organization.

The initial purpose of this experiment was to employ this technique to examine how extensively higher order units occur, their sequential properties, and the effects of certain free-recall variables on the development of such units. To demonstrate the inadequacy of pair-wise measures requires not only the existence of higher order units, but more importantly they must be shown to vary in internal structure from trial to trial. If there are no differences between the 3 sequential ordering criteria, then pair-wise sequential measures would appear adequately sensitive.

A second major problem concerns the relationship of free-recall acquisition performance (mean recall) to the amount of organization. Several different types of organizational processes have been shown to function in free recall, e.g., primacy and recency effects (Tulving, 1968), priority of recall of newly learned items (Battig, Allen, & Jensen, 1965), taxonomic clustering (Bousfield, 1953), SO (Tulving, 1962), and correspondence of recall order with list presentation order (input–output organization or seriation, Mandler, 1969). Investigations of the nature of any relationships between organization and recall have been severely handicapped by their reliance upon only one type of organizational measure and the failure to consider other viable types of organization or changes in organization occurring with practice. Thus the inconsistencies in this literature may be a function of a complex interactive relationship between several different modes of organization occurring simultaneously, any one of which is capable of producing recall differences. It might also be the case that increases in one type of organization occur at the expense of other types of organization. Thus the present study also provides a detailed examination and comparison of all the aforementioned types of organization, in order to evaluate their interactive nature, their relative importance as a function of different experimental variables, and any changes over trials in the usage of various processes. Also examined is the relationship(s) of these various types of organization to recall performance.

Two of the 3 variables in this stu (categorical vs. unrelated word lists a fixed vs. random presentation orders) have been previously examined with respect to SO. Puff (1970) failed to find any differences between categorical and unrela word list when measuring pair-wise S The list-order variable has been examined in lists of related and unrelated materials (e.g., Winograd, Conn, & Rand, 1971). Both the acquisition and organizational data indicate a facilitative effect produced by a fixed serial order for unrelated words, but little or no effect for related materials. It was hypothesized that both the list structure and the list-order variable should produce large effects on SO and therefore provide the necessary test of the existence and sequential consistency of higher order units. The third variable, not previously examined in free-recall tasks, involved a categorization pretest procedure given to half of the *S*s. Developed by Loftus and Scheff (1971), this pretest provided *S*s with words later used in the actual free-recall list to which *S*s produced the labels of categories which each word represented.

Method

Design and materials. The design of this experiment was a 2 × 2 × 2 factorial manipulating list structure (taxonomic or unrelated), presentation order (fixed or random), and categorization pretest (pretest or no pretest). The 25-item taxonomic list consisted of 5 items from each of 5 taxonomic categories (animals, clergy, metals, instruments, parts of the body), with all items high in taxonomic frequency (Battig & Montague, 1969). The 25-item unrelated list consisted of high taxonomic frequency items chosen from 25 different categories. In both lists there were the same 16 initial letters, and the Kucera and Francis (1967) word frequency was also equal. There were 6 different orders of each list with 5 used for the learning task and the other used for the pretest and posttest. In the taxonomic list, no 2 items from the same taxonomic category ever appeared in adjacent sequential positions, and in both lists each word appeared in each fifth of the list across the 5 random orders used for learning. For the random order conditions, each of the 5 different list orders was used equally often as the first-trial order, thus counterbalancing the random list order sequences in a 5 × 5 Latin square. Within the fixed-order conditions, each of the 5 different list orders was also used equally often for different *S*s, thus equating fixed and random conditions with respect to frequency of occurrence of each of the 5 list orders.

Apparatus and procedure. All *S*s were seated at a table and presented a test booklet containing 12 blank pages. They were instructed that they would see a list of words, one at a time at a 3-sec. rate, and that when they saw the words START RECALL they were to turn to the next blank page in their booklet and write as many words from the list as they could in any order they wished. They were further instructed that they had 1½ min. to do so and this procedure would continue for several trials. The list acquisition lasted for 12 trials. Under pretest conditions, *S*s were first taken to a different room and instructed that they would hear a list of words one at a time at a 10-sec. rate. They were asked to write on each new page of the small booklet provided as many category labels as they thought were appropriate to that word. Immediately following the pretest, these *S*s were taken into the experimental room and participated in the experimental task. Following the 12 free-recall trials, all *S*s were given a posttest identical to that given in the pretest conditions.

Subjects. There were 120 *S*s with 15 in each of the 8 conditions. All *S*s were University of Colorado students fulfilling a course requirement for experimental participation. Each *S* was tested for 50–60 min. in groups of 1–3. These *S*s were assigned to conditions using a block randomization procedure which assured that within each block of 8 test sessions each condition appeared once, and that within the first 40 test sessions each of the 5 counterbalancing orders for each condition appeared once. Following the first 40 test sessions, *S*s were assigned to conditions to complete the counterbalancing of list orders for those conditions where less than 3 *S*s had served in the initial session.

There were 4 *E*s, each testing approximately the same number of *S*s in each condition. There was a loss of 10 *S*s due to equipment problems or failure to follow instructions.

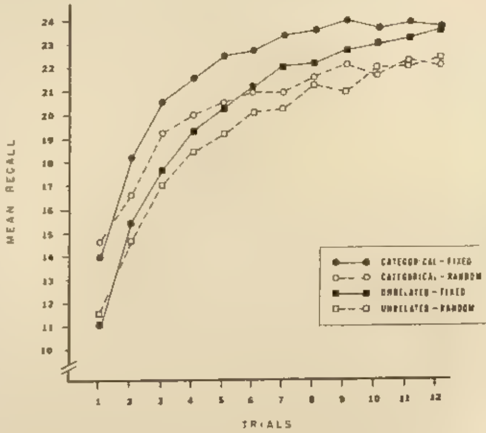

FIGURE 1. Mean recall as a function of list structure, list order, and trials.

Results

The minimum significance level for the mean recall and various organizational analyses that follow was .01. All main effects or interactions not specifically discussed in any of these sections did not reach this criterion. In each section that follows, the results are both described and related to previous empirical findings.

Acquisition. The basic recall results are presented in Figure 1. Mean recall was higher for categorical than unrelated list conditions, $F\ (1, 112) = 9.86$, and for fixed- than random-order conditions, $F\ (1, 112) = 8.62$. These differences decreased and increased, respectively, with trials, *F*s $(11, 1232) = 6.90$ and 3.31. No other interactions involving either variable approached significance. A large Pretest × Trials interaction, $F\ (11, 1232) = 10.00$, was primarily due to superiority of pretest over no-pretest conditions on the first 2 trials (15.76 vs. 13.25) and no effect thereafter (21.43 vs. 21.56), with this comparison accounting for 80% of the interaction variance.

TABLE 1

Mean Output-Output and Input-Output ARC′ Scores as a Function of Unidirectional and Unordered Criteria, Unit Size, and Point in Learning

Trials	Output-output			Input-output		
	Unidirectional	Unordered	Difference	Unidirectional	Unordered	Difference
Unit Size 2						
First half	.178	.265	.087	.069	.079	.010
Second half	.267	.372	.105	.105	.118	.013
Unit Size 3						
First half	.073	.159	.086	.038	.049	.011
Second half	.132	.258	.126	.085	.105	.020
Unit Size 4						
First half	.038	.105	.067	.026	.031	.005
Second half	.104	.208	.104	.073	.090	.017
Unit Size 5						
First half	.026	.077	.051	.020	.024	.004
Second half	.08[illegible]	.168	.084	.069	.081	.01[illegible]

These recall results are in general agreement with previous investigations (e.g., Mandler, 1969; Winograd et al., 1971). The one discrepant result was the facilitation by a fixed serial order within categorical lists. Mandler failed to find such facilitation, but obvious ceiling effects occurred in his 16-item lists. The failure of Winograd et al. to find such an effect may be due to the relatively short number of trials (4) since the present data indicate that this facilitation only occurs in later stages of learning. Thus the present results appear reconcilable with previous findings.

Ordering criterion effects. Initial analyses of both output-output and input-output organization ARC′ [illegible] scores [illegible] [illegible] 3 experimental variables, trials, and the 3 ordering criteria, and were performed separately for Unit Sizes 2–5.[3] This section is concerned with differences between the unidirectional and unordered criteria in sensitivity as organizational measures.[4]

Table 1 summarizes ordering criterion differences for both types of organization separately for each unit size. The values in Table 1 are pooled across all experimental conditions since all showed a similar pattern of results and any interactions

[3] Unit sizes were examined separately due to differences in the range of ARC′ scores that actually could be obtained. Although the theoretical range for ARC′ scores is identical for all unit sizes, any deviation from perfect sequential ordering (upon which the maximum observed values are based) produces larger reductions in the range of actual possible observable repetitions for the larger unit sizes, thereby reducing the functional range of ARC′ scores more severely for higher order unit sizes. For example, a single departure from perfect sequential consistency of 11 recalled items can produce ARC′ scores for units of Size 5 ranging .86–.29, while for units of Size 2 this would range only .90–.80 (depending on how close the discrepant item is to either end of the sequence). Any comparison across unit sizes involving the absolute numeric ARC′ score would therefore be misleading and to avoid such problems in interpretation separate analyses were performed on each unit size.

[4] Only unidirectional and unordered values are compared in this analysis due to the necessary identity of bidirectional and unordered scores for Unit Size 2, and data clearly showing that unidirectional and bidirectional values did not differ for Unit Sizes 3–5.

involving experimental conditions only reflected differences in the magnitude of the ordering criterion effect. The present discussion focuses only on the overall ordering criterion differences and a subsequent analysis will deal with the experimental conditions. The output–output analysis showed highly significant differences between criteria for all 4 unit sizes, $Fs\ (1, 112) > 206.65$. All 4 unit sizes also produced Ordering Criterion × Trials interactions, $Fs\ (10, 1120) > 3.56$. A subsequent breakdown of these interactions into first and second half of learning (as shown in Table 1) showed that the unidirectional–unordered difference was greatest in the second half of learning, particularly for the larger unit sizes, yielding $Fs\ (1, 1120)$ of 5.87, 8.98, 29.30, and 38.42 for Unit Sizes 2–5, respectively. In the input–output organization analyses, significant ordering criterion differences also occurred, $Fs\ (1, 112) > 23.42$, but these did not interact significantly with trials.

These ordering criterion effects indicate quite strongly that the unordered criterion is the most sensitive for determining the total amount of organization based upon either the previous recall order or the present list order. They further indicate that when *S* is using prior recall as a basis for determining present recall order, such organizational units vary considerably in sequential consistency, particularly for larger unit sizes late in learning. Thus simple pair-wise sequential measures necessarily underestimate the total amount of organization, so units larger than Size 2 must be examined to determine the effects of experimental variables upon SO. When *S* is basing recall order on the list presentation order, however, organizational units vary less in internal sequential consistency and this does not change over trials.

As noted previously, the ordering criterion difference also interacted with experimental conditions and these interactions generally showed that any differences between experimental conditions were primarily a function of the unordered values, particularly in the larger unit-size analyses. Since the unordered criterion more adequately represents and is more sensitive to the total amount of organization that has occurred, the analyses that follow are based upon only the unordered criterion scores.

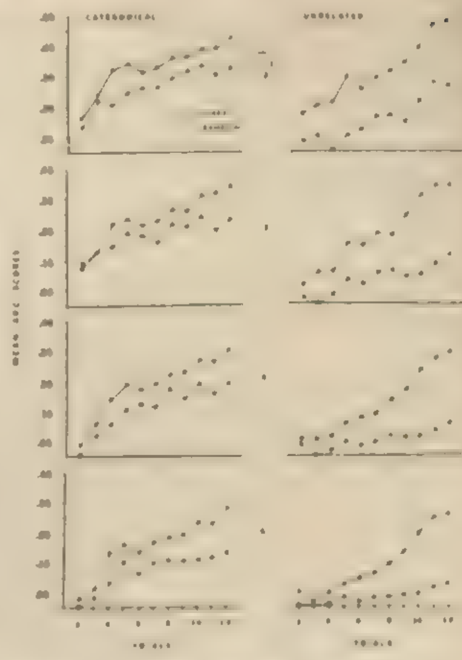

FIGURE 2. Mean unordered output–output organization for Unit Sizes 2–5 as a function of list structure, list order, and trials.

Output–output. The major results of these analyses are shown in Figure 2. The pretest variable had no effect in this or any other organizational analyses that follow, and will not be discussed further in those sections. Figure 2 shows overall significant increases in organization over trials for all 4 unit sizes, $Fs\ (10, 1120) > 24.25$. Differences between categorical and unrelated list conditions were found only in the analyses of Unit Sizes 3, 4, and 5, $Fs\ (1, 112) > 8.91$. Interactions between this list structure variable and trials also appeared in the analyses for Unit Sizes 2, 4, and 5, $Fs\ (10, 1120) > 2.60$, reflecting maximal differences between categorical and unrelated conditions on Trials 4–10 with little difference on the first and last 2 trials. Figure 2 also shows large differences between fixed- and random-list-

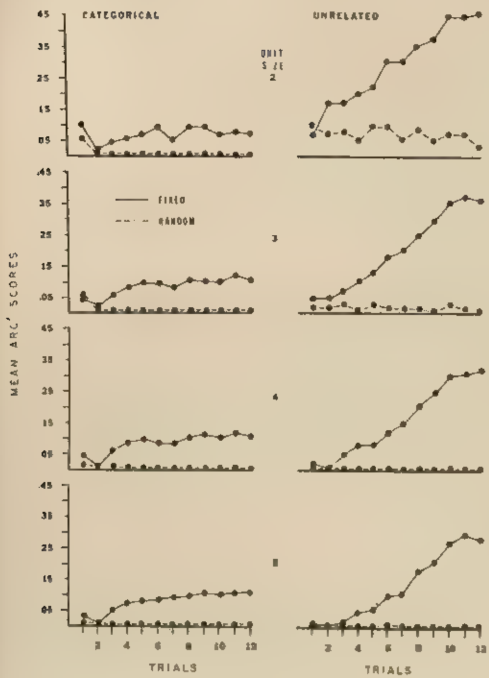

FIGURE 3. Mean unordered input-output organization for Unit Sizes 2–5 as a function of list structure, list order, and trials.

order conditions for all 4 unit sizes, *F*s (1, 112) > 13.45. However, List Order × Trials interactions only appeared in analyses for Unit Sizes 3, 4, and 5, *F*s (10, 1120) > 3.57, indicating increasing differences favoring fixed- over random-order conditions as learning progressed.

The present results for Unit Size 2 are consistent with previous data (e.g., Mandler, 1969; Puff, 1970). However, Puff's conclusion that the degree of SO is identical for randomized categorical and unrelated lists is contradicted by larger unit-size data. This result further indicates that pair-wise indices are relatively insensitive to the total amount of SO, particularly if that organization has a free-varying structure. Moreover, higher order unit-size measures produce differences more closely paralleling those for list acquisition, notably superiority of categoric over unrelated lists, and fixed over random orders especially on later trials. The latter results further indicate that higher order measures should be more closely related to between-groups recall differences, which would provide a strong argument for their usage. This was examined by computing separate correlations for recall with Unit Sizes 2 and 2 5. Pair-wise and multiple correlations based upon group means yielded respective values of .67 ($p > .05$) and .98 ($p < .001$). These correlations differed significantly, F (3, 3) = 12.92, $p < .05$ (McNemar, 1962, p. 284) thus demonstrating that higher order unit sizes contribute i tantly to recall differences between g

Similar correlation comparisons also made between *S*s within each present 4 major groups, as shown i ble 2. Higher order units clearly acc for more of the within-groups vari only for the categorical list, particularly in the categorical–random condition, F (3, 25) = 11.95, $p < .001$. By contrast, higher order units contributed nothing within unrelated-list conditions.

Input–output. The major results of these analyses are shown in Figure 3. Organization increased over trials in all 4 unit-size analyses, *F*s (11, 1232) > 6.63. Only Unit Size 2 yielded an overall effect of list structure, F (1, 112) = 28.45. However, all 4 unit-size analyses produced a significant List Structure × Trials interaction, *F*s (11, 1232) > 4.59, reflecting the increasing superiority of unrelated conditions with practice. Figure 3 also shows large differences favoring fixed- over random-order conditions which were significant for all unit sizes, *F*s (1, 112) > 14.43. There was a significant List Order × Trials interaction in all analyses, *F*s (11, 1232)

TABLE 2

SIMPLE AND MULTIPLE CORRELATIONS BETWEEN MEAN RECALL AND ORGANIZATION UNIT-SIZE MEASURES

Condition	Unit size			
	2	2, 3	2, 3, 4	2, 3, 4, 5
Categoric–random	.45*	.45*	.70**	.82**
Categoric–fixed	.21	.25	.26	.34
Unrelated–random	.65**	.65**	.65**	.66**
Unrelated–fixed	.47*	.47*	.48*	.49*

* $p < .01$.
** $p < .001$.

> 12.48. As shown in Figure 3, this increasing fixed-random difference over trials was limited to unrelated-list conditions, yielding Fs (11, 1232) > 3.98.

The input–output data for the unrelated conditions are consistent with Mandler and Dean's (1969) results. However, the present level of input–output organization for categorical–fixed conditions is well above that reported by Mandler (1969), who concluded that no *S*s in this group showed a seriation tendency. The present data indicated that at least 2 of 30 *S*s in the categorical-fixed group showed perfect seriation, although this in itself could not account for the mean level of performance exhibited. Another difference from Mandler was the present failure to find any taxonomic clustering superiority of the categorical–fixed condition relative to the categorical–random condition which indicates that seriation may be used in lieu of or in addition to taxonomic organization in typical categorized lists. Mandler's failure to find a seriation tendency in this group is probably because his *S*s were completely instructed about the taxonomic list structure before learning.

Primacy–recency. The input–output analyses assess the role of serial input order as a general determinant of recall order, but provide no information about the relative position of these items in the recall order or recency and primacy determinants of recall order. To determine any such effects, an adaptation of the standarized recall rank measure (Battig et al., 1965) was used, whereby positive and negative values, respectively, indicate mean recall positions before or after the median on that trial. Although obtained for each fifth of the list on each trial, only the primacy and recency components showed significant effects, so these alone will be discussed here.

As shown in Figure 4, primacy and recency components showed no significant overall differences with respect to position in recall, but there was a significant Primacy–Recency × Trials interaction, F (11, 1232) = 11.03. All 4 panels of Figure 4 show this interaction to reflect

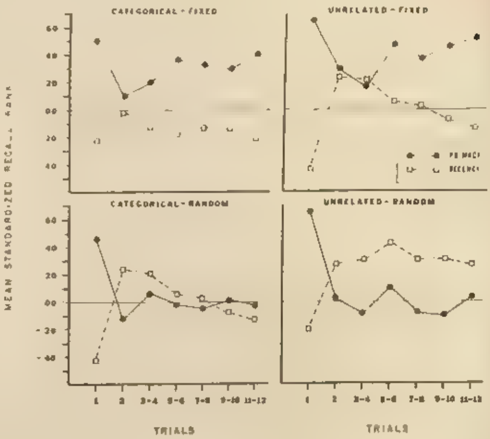

FIGURE 4. Mean standardized recall rank values for primacy and recency components of list order as a function of list structure, list order, and trials.

the large primacy–recency difference on Trial 1 which is reduced and reversed on Trial 2. Figure 4 additionally shows that this Primacy–Recency × Trials interaction depended upon list presentation order, F (11, 1232) = 2.52. Significant also was the opposite direction of this primacy–recency difference for fixed- (.43) and random-order conditions (−.15). The final significant effect was the overall difference between categorical and unrelated lists, F (1, 112) = 24.63, indicating that the pooled primacy and recency components occurred earlier in recall in the unrelated- (.18) than categorical-list (.07) conditions.

The results of this analysis are in general agreement with those studies (e.g., Deese & Kaufman, 1957) using correlational techniques to demonstrate a recency strategy. However, the present technique indicates that there are 2 factors determining the occurrence of such a strategy. The first factor is experience in the experimental situation, such that a naive S does not demonstrate any recency effect until Trial 2. The second factor concerns the maintenance of such a strategy which depends on both the list structure and list order, since consistent recency only occurs in unrelated–random conditions where no semantic or serial position cues are provided. The primacy component results

are in agreement with Mandler and Dean (1969) who found that unrelated constant serial order lists contain a constant primacy component, and also extend this result to categorical–constant serial order lists. The latter results also indicate the sensitivity of this organizational technique for studying primacy and recency effects.

Priority. The Battig et al. (1965) procedures were also applied to the analysis of priority of recall of newly learned items (PRNI). Items were considered as new items only if never recalled previously. This analysis was performed only on Trials 2–6 inclusive since no new items occurred following Trial 6. Included in this analysis were the variables of item type (old vs. new) and trials in addition to the experimental variables. Much higher priority was given to new items (.19) than to old items (−.19), F (1, 112) = 178.82. An Item Type × Trials interaction, F (4, 448) = 3.97, reflected increasing priority scores for new items across Trials 2–4 (.20, .25, and .34, respectively) which decreased on Trials 5 and 6 (.08 for both), while the priority scores for old items remained stable across all trials (—.22, —.20, —.18, —.17, —.18, respectively).[5] There was a List Order × Item Type interaction F (1, 112) = 10.06, reflecting no difference in the rank of old items for either type of list order, but a much higher priority for new items under the random- (.27) than fixed-order (.10) conditions. A similar List Structure × Item Type interaction, F (1, 112) = 6.79, resulted from a much higher priority given to new items under the unrelated (.26) than the categorized (.12) conditions but no such difference for old items.

The present PRNI effect suppo[rts] strongly several previous studies demo[n]strating such an effect (e.g., Battig [&] Slaybaugh, 1969). Of particular interest however, is the limitation of this PRNI effect both with categorical structure and fixed serial orders. As in the present analysis of recency, this mode of organization seems to suffer when semantic or serial list cues are present.

Discussion

The present analyses of higher order SO units have demonstrated that such units are formed in typical free-recall learning, and more importantly, that they vary in their sequential reproduction across trials. These data therefore support the contentions that pair-wise sequential indices are insensitive and underestimate total SO. The insensitivity problem was further illustrated by the 96%–45% difference in the amount of between-groups recall variance that could be accounted for by using all unit sizes as opposed to Size 2 alone.

The failure to observe similar correlation increases within groups, with the exception of the categorical–random condition, provides further information about the structure of recall and the relationships among unit-size measures. Since *S*s in fixed-order conditions relied on input order as a basis of organization, thereby reducing the internal sequential variability in organization units (see Table 1), any higher order organization should be almost completely measured by Size 2 units. Correlations between pair-wise and higher order unit sizes were above .925 thus supporting this interpretation. In the unrelated–random conditions it is probably the delayed development of higher order units rather than any strong relationships between unit-size measures (all rs $< .690$) that caused the correlations to remain constant. Support for this interpretation comes from similar analyses based on the last 2 trials whereby the correlation increased from .601 to .721 by the addition of Size 3 units, producing a marginally significant difference ($p < .10$). Stronger evidence that higher order units enhance between-*S*s organization-recall relationships within unrelated–random lists comes from a similar analysis of previous data (Rogers & Battig, 1972). This showed a correlation of −.001 for pair-wise units which increased significantly to .454 when units of Size 3 were included.

[5] In the standardized recall rank technique, sets of items comprising the total recall on that trial are compared with respect to position in recall. Only when the sets are nearly equal in size does the mean of the standardized recall rank values obtained across all sets necessarily approach 0. However, as the sets become increasingly disproportionate in size (as when old exceed new items after Trial 2), the mean standardized recall rank values across all sets can differ substantially from 0.

The overall correlational data indicate that fairly strong recall-organization relationships may operate for the higher order units, although substantial between-*S*s variability in recall within groups remains unaccounted for by such relationships. Part of this variability can be attributed to the existence of several different types of organizational processes which occur simultaneously, often in reciprocal relationship to one another, and which can affect recall. Evidence of such reciprocal relationships is provided by the findings of (*a*) more SO but less overall primacy, recency, and priority-of-new-item effects within categorical than unrelated lists, and (*b*) more SO for fixed- than random-order conditions but with less priority of new items and also a reduced recency strategy.

Besides showing an overall reciprocal relationship between processes, the data also indicate that such relationships change with practice. A hierarchy of organizational strategies or series of stages is evident such that *S*s begin with a strong seriation strategy on the first trial followed by recency and priority strategies, and culminating in higher order SO processes. The main difference between conditions appears to be in the second and third stages of this organizational development. In those conditions where there is an interitem semantic relationship, or a fixed serial order, or both, the degree to which priority and recency strategies are developed is limited and these *S*s appear to proceed more rapidly to an organizational stage involving the formation of higher order *S* units. Only in the unrelated–random condition do *S*s maintain a recency strategy and show little development of higher order SO units, thus contradicting Puff's (1972) conclusion that recency might facilitate SO in unrelated lists. It appears that higher order units per se are not sufficient to explain recall differences, and that overall speed or ease of transition to this stage is equally important. Without semantic or sequential cues, *S*s may be forced to operate with simpler organizational strategies.

Based on the foregoing evidence of the interactive nature of organizational processes and changes in such processes over trials, previous inconsistencies in the recall-organization literature appear due to at least 2 factors, i.e., (*a*) inability of any one index to account for the complete pattern of organization and (*b*) differences in this pattern depending on degree of practice.

An important additional consideration with respect to the present results concerns their relationship to storage and retrieval processes. One apparently unresolved issue is whether the organization observed at output is a function of storage, retrieval, or both. Slamecka's (1968, 1969) tests of the independent storage hypothesis were based upon list organization of items by pairs, i.e., the organizational units could be represented by direct associative relationships between pairs of list items. The present data question the validity of this assumption and his tests of the independence hypothesis. Additionally, given that higher order units are formed, one must question what constitutes the appropriate accessibility cue for any individual list item. The general lack of success of studies which have attempted to use individual list item cuing may be a function of this problem.

Given that higher order free-varying units are formed, one can also wonder which current theories of storage and retrieval would predict such structures. The development of such units is consistent with the hierarchical model of Mandler (1967) although he did not state how recall should occur within or between units. A random selection process at all levels of the hierarchy would produce the desired results and would be similar to Shiffrin's (1970) restricted search hypothesis. An alternative theory based upon an associative network (Anderson, 1972) might also produce organization results similar to those observed. In addition, Anderson's model would predict that the formation of higher order units is a direct result of storage and the elaboration of the associative graph. Since this graph changes from trial to trial, organizational units could be maintained although the order within such units might vary. The output protocols produced by Anderson's model would have to be analyzed for units larger than 2 to more fully determine the adequacy of the model.

Also, while it may be relatively easy to predict the sequential organization properties of recall protocols via random selection within and across units, it is more difficult to hypothesize how such random units are formed. Wallace (1970) has speculated that the pairwise organization typically measured is a function of implicit and explicit contiguity during learning. Such a theory must ultimately be able to explain the free-varying internal structure of higher order units in random-list-order conditions and the reduced variability under constant-order conditions. A comparison of Anderson's (1972) and

Wallace's associative theories seems to be required to help resolve how such units are formed, what circumstances dictate their formation, and whether any associative theory is capable of explaining them. Irrespective of specific issues, the present organization results certainly must be dealt with in any complete theory of storage and retrieval processes.

SEQUENTIAL EFFECTS IN DISCRETE-TRIALS INSTRUMENTAL ESCAPE CONDITIONING

JEFFREY A. SEYBERT, ROGER L. MELLGREN, JARED B. JOBE, AND ED ECKERT

University of Oklahoma

Five experiments investigated both acquisition and extinction effects in a discrete-trials (runway) escape paradigm. The escape procedure consisted of shocking *S* in the start and run sections of the runway, and reducing shock level in the goal box on reinforced (R) trials but not on nonreinforced (N) trials. The results of these experiments were: (*a*) greater resistance to extinction was exhibited by partially reinforced *Ss* than continuously reinforced *Ss*, (*b*) presence and number of N-R transitions influenced resistance to extinction, (*c*) number of successively nonreinforced trials (N length) was also a determinant of resistance to extinction, and (*d*) alternating N and R trials resulted in patterned running, but a double-alternation schedule did not. The results of all 5 experiments were interpreted as sup-[illegible] 1967 [illegible] extended to include instrumental escape conditioning phenomena.

Capaldi's (1967) sequential hypothesis of instrumental learning has received considerable support when appetitive instrumental conditioning procedures are used (e.g., Robbins, 1971). Relatively little work has been reported, however, investigating sequential variables in aversive conditioning paradigms, although there is some evidence to indicate that sequential factors are important in determining response persistence in punishment situations (e.g., Campbell, Wroten, & Cleveland, in press; Capaldi & Levy, 1972; Dyck, Mellgren, & Nation, 1974). It was the purpose of the present experiments to investigate the operation of sequential variables in instrumental escape conditioning and to determine if it is possible to extend the boundary conditions of sequential theory to an area of research where they previously have not been applied.

Recently, Franchina and his co-workers (e.g., Franchina & Snyder, 1970) have reported several escape conditioning experiments in which the sequence of shock and nonshock trials was manipulated in a hurdle-box apparatus. A shock trial consisted of shock present in 1 side of the apparatus, and a nonshock trial consisted of the absence of shock in both sides of the apparatus. These authors and others (e.g., Woods, Markman, Lynch, & Stokely, 1972) have noted, however, that these data cannot be explained in terms of the sequential effects of reinforcement and nonreinforcement because the shock-nonshock procedure is not analogous to reward-nonreward trials in the appetitive situation, since there is a lack of primary motivation on the nonshock trials. Thus, in order to test the effects of sequential variables in instrumental escape conditioning, it would be necessary to utilize procedures analogous to rewarded and nonrewarded trials in appetitive instrumental conditioning. For example, in a runway, a "rewarded" escape trial would consist of the application of some aversive stimulus to *S* in the start and run sections of the straight runway and the absence (or reduced level) of that aversive stimulus in the goal box. A "nonrewarded" escape trial would consist of the application of the same aversive stimulus in all sections of the runway. It should be noted that the duration of nonreward must necessarily be limited in this procedure because at some time after *S* enters the goal box it must be removed. Thus, the above procedure may be more analogous to delay of reward, but since both nonreward and delay have been postulated to involve similar theoretical mechanisms (Capaldi,

[1] Requests for reprints should be sent to Roger L. Mellgren, Department of Psychology, University of Oklahoma, Norman, Oklahoma [illegible]

1967) the terminology of nonreward will be maintained.

One prediction of sequential theory that has been confirmed in appetitive studies involves the Schedule of Reward × Number of Acquisition Trials interaction. Following limited acquisition, reward schedules with N lengths—number of consecutive nonreinforced (N) trials followed by a reinforced (R) trial—of 1 produce greater resistance to extinction (Rn) than do schedules with longer N lengths; but after extended acquisition training, reward schedules with long N lengths produce greater Rn than do schedules with N lengths of 1 (see Capaldi, 1967) when percentage of reinforcement is equated for the 2 groups. Experiments I and II represent an attempt to demonstrate this interaction using an escape conditioning procedure.

Experiment I

Following limited acquisition training, a group receiving N lengths of 1 should show greater Rn than a group receiving N lengths of 3, because there should be greater strength of the association between the memory of nonreward and the instrumental response (S^N–R_I in sequential terminology) for the N length 1 group due to the greater number of transitions from nonreinforcement to reinforcement (N–R transitions) that occur when percentage of reinforcement is equated. Both partial reinforcement (PRF) groups should show more Rn than the continuous reinforcement (CRF) control group.

Method

Subjects. The *S*s were 36 experimentally naive male albino rats of the Sprague–Dawley strain, purchased from the Holtzman Co. They were approximately 100 days old at the start of training and were randomly assigned to 1 of 3 groups (n = 12/group).

Apparatus. The apparatus consisted of a straight-alley runway manufactured by the Hunter Co. The alley was constructed of clear Plexiglas with a grid floor and was 150 × 15 × 9 cm. It was divided into a 30-cm. start section, a 90-cm. run section, and a 30-cm. goal section, with all sections separated by guillotine doors. The *S*s' progress in the alley was measured by 3 .01-sec. Standard timers: the first, which measured start time, was started by a microswitch at the start-box door and stopped by a photocell located 11 cm. into the alley; the second, which measured run time, was started by the first photocell and stopped by a second photocell located 11 cm. in front of the goal box; the third, which measured goal time, was started by the second photocell and stopped by a third photocell located 9 cm. inside the goal box. Start, run, and goal speeds were obtained by converting the start, run, and goal times to reciprocals. A .3-ma. scrambled shock was automatically delivered to the start and run sections of the alley by a Model 700 Grason Stadler shock generator, which was activated by the microswitch at the start-box door. Shock of the same strength could be administered manually to the goal section of the alley by means of a switch mounted on the apparatus control panel. This apparatus was also used in Experiment II.

Procedure. Upon arrival in the laboratory, *S*s were individually housed and placed on an ad-lib schedule of food and water which continued throughout the experiment. During the 3 days before the start of the experiment, each *S* was handled for 5–10 min. daily. One day of pretraining preceded the actual start of the experiment. During this period, all *S*s received 2 R trials in the apparatus. The following procedure was employed throughou[illegible] the experiment on R trials. The *S* was pl[illegible] in the start box, and after a peri[illegible] start-box door was raised, activat[illegible] timer and the shock generator. [illegible] traversed the runway and entere[illegible] trified goal box, the goal-box door was closed and *S* was confined for 15 sec., after which it was removed and placed in a carrying cage. The procedure on N trials was simila[illegible] R trials except that as soon as *S* left the [illegible] box, *E* depressed the switch which electrified the grid floor of the goal box with a .3-ma. shock. When *S* entered the goal box, the door was closed and it was confined to the electrified goal box for 15 sec., after which it was removed to the carrying cage. Thus, reinforcement consisted of a 15-sec. confinement in the nonelectrified goal box following shock in the start and run sections, while nonreinforcement consisted of a 15-sec. confinement in the electrified goal box following shock in the start and run sections.

Acquisition training consisted of 8 trials per day for 2 days, a total of 16 acquisition trials. Two groups received a 62% PRF schedule in the escape apparatus, while the third group (Group CRF) was reinforced on all trials during acquisition. Group 1N had 3 N trials in each daily session, each N trial being followed by at least 1 R trial. The acquisition reward schedule for Group 1N was as follows: Day 1, RRNRNRNR; and Day 2, RNRNRRNR. Group 3N also received 3 N trials in each daily session, but the N trials occurred consecutively. The acquisition reward schedule for Group 3N was as follows: Day 1, RRNNNRRR; and Day 2, RRRNNNRR. The *S*s were run in

squads of 3 with an intertrial interval (ITI) of 3–4 min.

After acquisition training, all *S*s were given 4 extinction trials per day for 3 days, a total of 12 extinction trials. The procedure for extinction trials was the same as for the N trials during acquisition.

Results and Discussion

In the 5 experiments reported here, data from all runway sections were examined. However, the most consistent and reliable effects were observed in the start-speed measure, and therefore all analyses reported and discussed in this and subsequent experiments will be in reference to start speeds.

An analysis performed on the last block of 8 acquisition trials indicated no terminal acquisition differences, $F\ (2,\ 33) < 1$. A 3×4 (Groups $\times$ Days) analysis of variance performed on the start-speed data for the last day of acquisition and the 3 days of extinction revealed a significant days effect, $F\ (3,\ 99) = 3.96$, $p < .025$; a marginally significant groups effect, $F\ (2,\ 33) = 2.82$, $p = .07$; and a nonsignificant Groups $\times$ Days interaction, $F\ (6,\ 99) < 1$. Sequential theory makes a specific prediction concerning the rank ordering of the groups following limited acquisition: Group 1N should demonstrate greater Rn than Group 3N, and Group 3N should be more resistant than Group CRF. This prediction was tested by a Jonckheere (1954) test. The Jonckheere procedure tests the null hypothesis that groups are not significantly ranked in a specific predicted order, and thus it is ideally suited for examining the predictions of sequential theory in the present experiment. Results of the Jonckheere test performed on the sums of start speeds for the 3 days of extinction indicated than the groups demonstrated the predicted rank ordering, $z = 2.20$, $p = .01$. The data from Experiment I may be seen in Figure 1.

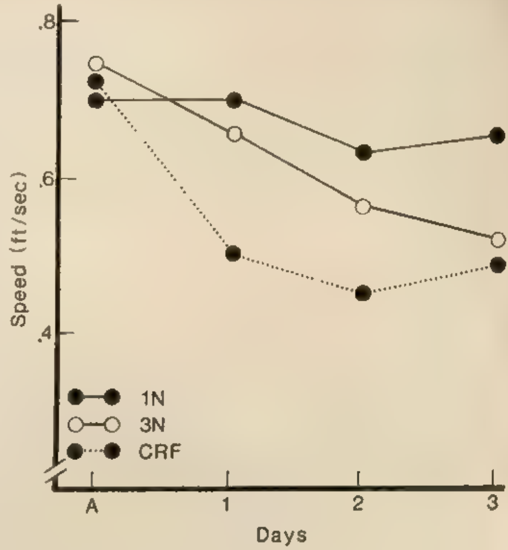

FIGURE 1. Mean start speeds for the last day of acquisition (A) and 3 days of extinction.

The results of Experiment I revealed that one portion of the Schedule of Reward $\times$ Number of Acquisition Trials interaction found in appetitive conditioning also occurs in instrumental escape conditioning. Specifically, following a limited number of acquisition trials, a group receiving short N lengths in acquisition was more resistant to extinction than a group receiving longer N lengths during acquisition. This finding supports the prediction made from sequential theory.

EXPERIMENT II

According to sequential theory, after extended acquisition, it would be predicted that a group receiving N lengths of 3 in the instrumental escape procedure should show more Rn than a group receiving N lengths of 1, because the strength of the hypothetical S^N–R_I association would be asymptotic for both groups, and the N Length 3 group would experience less generalization decrement in extinction.

Method

Subjects. The *S*s were 36 experimentally naive male albino rats of the Sprague-Dawley strain purchased from the Holtzman Co. They were approximately 85 days old at the start of the experiment and were randomly assigned to 1 of 3 groups ($n = 12$/group).

Procedure. After arrival in the laboratory, *S*s were individually housed and placed on ad-lib food and water. As in Experiment I, *S*s were handled individually for 3 days prior to the start of the experiment and were given 2 reinforced trials in

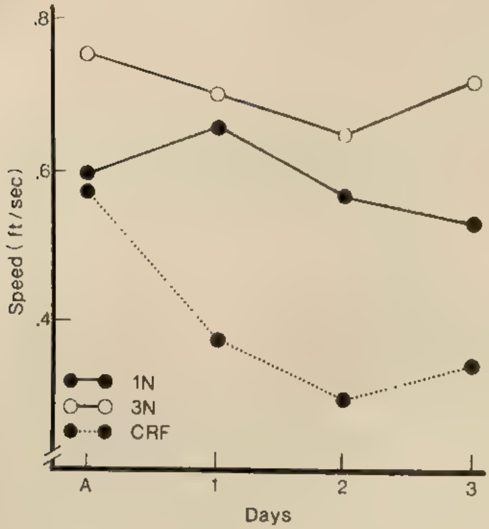

FIGURE 2. Mean start speeds for the last day of acquisition (A) and 3 days of extinction.

the runway as pretraining. The procedure for R and N trials was exactly the same as in Experiment I.

Acquisition training consisted of 8 trials per day for 5 days, a total of 40 acquisition trials. Two groups had a 62% PRF schedule, while the third group (Group CRF) was reinforced on all trials in acquisition. Group 1N had 3 N trials in each daily session, each N trial being followed by an R trial (3 N lengths of 1). Group 3N also had 3 N trials in each daily session, but the N trials occurred consecutively (1 N length of 3). The actual sequence of trials in acquisition for all groups may be seen in Table 1. Throughout the experiment, *Ss* were run in squads of 3 (1 from each group), with the ITI being approximately 3–4 min. for each *S*.

Upon completion of acquisition training, *Ss* were given 12 extinction trials, 4 per day for 3 days. The procedure for all extinction trials was the same as for the N trials during acquisition.

Results and Discussion

The analysis performed on start speeds for the last block of 8 trials in acquisition

TABLE 1

SEQUENCE OF REINFORCED (R) AND NONREINFORCED (N) TRIALS FOR ALL GROUPS DURING ACQUISITION

Day	Group		
	1N	3N	CRF
1,5	RRNRNRNR	RRNNNRRR	RRRRRRRR
2	RNRNRRNR	RRRNNNRR	RRRRRRRR
3	RNRRNRNR	RNNNRRRR	RRRRRRRR
4	RNRNRNRR	RRRRNNNR	RRRRRRRR

indicated no terminal acquisition differences, F (2, 33) < 1. A 3 × 4 (Groups × Days) analysis of variance performed on the start speeds for the last day of acquisition and the 3 days of extinction revealed a significant main effect for days, F (3, 99) = 3.51, p < .02, as well as a significant groups main effect, F (2, 33) = 3.89, p < .03. The Groups × Trials interaction failed to reach an acceptable level of significance, F (6, 99) = 1.38, p > .10. The Jonckheere test performed on the sums of the start speeds for 3 days of extinction indicated that the groups were rank ordered as predicted, z = 3.00, p = .001. The data for Experiment II may be seen in Figure 2.

The results of Experiment II indicated that the second part of the Schedule of Reward × Number of Acquisition Trials interaction, commonly found in appetitive conditioning and predicted by sequential theory, is also observed in instrumental escape conditioning. Following extended acquisition, the group receiving N lengths of 3 showed greater Rn than the group receiving N lengths of 1.

EXPERIMENT III

Although the results of Experiments I and II were statistically reliable, they might be seen as somewhat unimpressive, and it was deemed desirable that these effects be systematically replicated and extended, as there is a paucity of data concerning extinction effects in escape conditioning. Therefore, Experiment III represents an attempt to again demonstrate the effects of differential N lengths following limited acquisition, using different procedural parameters.

The procedural changes in the present experiment were made on the basis of unpublished work in the authors' laboratory which indicated that such changes might produce more clearly delineated results. These changes were: (*a*) an increase in the level of shock, (*b*) an increase in the reinforcing amount of shock reduction, (*c*) the presence of a very low level of shock in the goal box on R trials, and (*d*) an increase in the goal-box confinement time

on both R and N trials. Finally, the continuously reinforced control group was omitted, since the PRF extinction effect in escape conditioning has been reliably demonstrated, both in Experiments I and II reported here and elsewhere (e.g., Bower, 1960; Woods et al., 1972).

Method

Subjects. The *Ss* were 16 experimentally naive male albino rats of the Sprague-Dawley strain, purchased from the Holtzman Co. They were approximately 110 days old at the start of the experiment and were randomly assigned to 1 of 2 groups (n = 8/group).

Apparatus. The apparatus was identical to that used in Experiment I with 1 exception. An automatic timer was included in the control panel to regulate shock and confinement time in the goal box. This apparatus was also used in Experiments IV and V.

Procedure. Upon arrival in the laboratory, *Ss* were housed 2 to a cage and placed on an ad-lib schedule of food and water which continued throughout the experiment. One day prior to the start of the experiment, each *S* was given 1 reinforced pretraining trial in the apparatus. The procedure on R trials was similar to that in the first 2 experiments except that the shock level in the start and run sections was .5 ma., the shock level in the goal box was .1 ma., and the goal-box confinement time was 30 sec. On N trials the shock level was the same (.5 ma.) in all sections, and goal-box confinement time was 30 sec. Thus, reinforcement consisted of a 30-sec. confinement in the .1-ma. electrified goal box following .5-ma. shock in the start and run sections (a .4-ma. shock reduction), while nonreinforcement consisted of a 30-sec. confinement in the .5-ma. electrified goal box following .5 ma. in the start and run sections (no shock reduction).

As in Experiment I, acquisition training consisted of 8 trials per day for 2 days, a total of 16 trials. The 2 groups (Group 1N and Group 3N) received 62% PRF in the apparatus, with the same schedules used for Group 1N and Group 3N as in Experiment I. The *Ss* were run in squads of 4 (2 *Ss* from each group per squad), with the ITI for each *S* being approximately 4 min. Following acquisition training, all *Ss* received 8 extinction trials per day for 2 days, a total of 16 extinction trials. The procedure for extinction trials was exactly the same as that for N trials during acquisition.

Results and Discussion

An analysis performed on start speeds for the last block of 8 acquisition trials indicated that there were no terminal acquisition differences, t (14) = .70, p > .05.

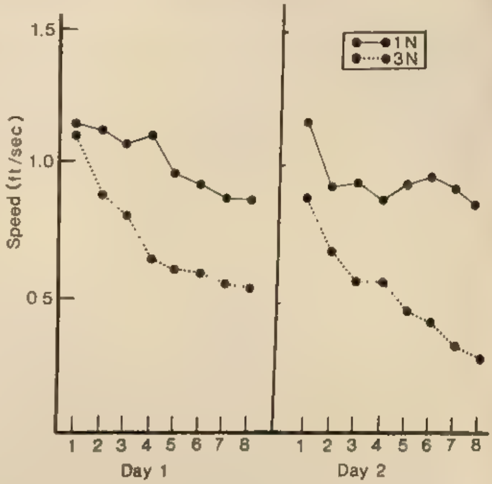

FIGURE 3. Mean start speeds for 2 days of extinction (8 trials/day, plotted trial by trial).

It can be seen from Figure 3 that the extinction results of this experiment closely parallel those of Experiment I and are also comparable to appetitive studies using similar procedures (see Capaldi, 1967): Group 1N showed greater response persistence than did Group 3N on both days of extinction. These conclusions were confirmed by separate 2 × 8 (Groups × Trials) analyses of variance performed on the start-speed data for each day of extinction. On Day 1 the groups main effect was significant, F (1, 14) = 5.24, p < .05; as well as the trials main effect, F (7, 98) = 8.44, p < .001; but the Groups × Trials interaction failed to reach an acceptable level of significance, F (7, 98) = 1.74, p > .10. On Day 2 the groups main effect was again significant, F (1, 14) = 15.74, p < .005, as was the trials main effect, F (7, 98) = 17.50, p < .001. Since there was a large difference between the groups on Trial 1 of Day 2, a significant Groups × Trials interaction would be necessary in order to demonstrate differential *rates* of extinction as opposed to simply differential amounts of spontaneous recovery. This interaction was significant, F (7, 98) = 7.92, p < .001.

Thus the finding that, following limited acquisition, short N lengths produce greater Rn than long N lengths is reliable

in instrumental escape conditioning. It should also be noted that the changes in procedure from Experiment I to the present experiment, i.e., increasing shock level, amount of shock reduction, and goal-box confinement time, seem to increase the magnitude of these effects.

Experiment IV

It has been demonstrated by a number of investigators using appetitive procedures (see Capaldi, 1967) that rats, if provided with a regular sequence of R and N trials, will learn to respond appropriately. That is, they will learn to run slowly on N trials and fast on R trials. It was the purpose of this experiment to investigate this phenomenon, known as patterned running or patterning, in an instrumental escape conditioning paradigm. Patterning has been demonstrated in appetitive conditioning when single-alternation schedules are used, i.e., alternation of N and R trials; however, patterning is not usually observed when double-alternation schedules are used, i.e., 2 N trials alternated with 2 R trials (e.g., Bloom & Capaldi, 1961). The present experiment utilized both single- and double-alternation schedules in order to determine if similar results hold using the instrumental escape procedure.

Method

Subjects. The *Ss* were 35 male albino rats of the Sprague–Dawley strain, obtained from the Holtzman Co. They were approximately 180 days old at the start of the experiment and were randomly assigned to 1 of 5 groups ($n = 7$/group).

Procedure. Throughout the experiment *Ss* were housed individually and maintained on an ad-lib schedule of food and water. One day prior to the start of the experiment, all *Ss* were given 2 reinforced pretraining trials in the apparatus. Reinforced and nonreinforced trials were conducted exactly as in Experiment III.

Acquisition training consisted of 4 trials per day for 30 days, a total of 120 acquisition trials. Four groups received a 50% PRF schedule during acquisition, while a fifth group (Group CRF) was reinforced on all trials during acquisition. The 4 PRF groups formed the cells of a 2 × 2 factorial with the factors being N length (1 or 2) and type of ordinal trial (N trial first or R trial first). Thus, the 4 PRF groups were labeled NRNR, RNRN, NNRR, or RRNN to denote their schedule of R and N trials on each day of acquis[...] were run in squads of 5, 1 *S* from [...] a squad, with an ITI of 5–6 min. for [...]

Following acquisition training, all [...] 4 extinction trials per day for 10 da[...] 40 extinction trials. The procedure [...] trials was exactly the same as that [...] trials during acquisition.

Results and Discussion

Acquisition. An analysis on the mean of all 4 trials of the last day in acquisition indicated no differences between the groups at the end of acquisition, F (4, 30) < 1. The start-speed data from the PRF groups for all days of acquisition were analyzed in order to determine if any patterning occurred. So that the data would not be contaminated by any possible first-trial warmup effect, the first trial of each day was not included in the analysis. The fourth trial of each day was also deleted in order to equate the number of N and R trials in the analysis. Thus, only the 2 middle trials for each day were analyzed. These data were combined into 3-day blocks and analyzed via a 2 × 2 × 2 × 10 (N Length × Type of Ordinal Trial—N First or R First × Type of Trial—N or R × Trial Blocks) analysis of variance. The type of ordinal trial main effect was nonsignificant, F (1, 24) < 1, and it did not interact with any other variables. The N length main effect also failed to reach an acceptable level of significance, F (1, 24) < 1, although the N Length × Type of Trial interaction was significant, F (1, 24) = 4.17, $p < .05$, as well as the N Length × Type of Trial × Blocks interaction, F (9, 216) = 3.52, $p < .001$. The main effect of type of trial was significant, F (1, 24) = 15.03, p = .001, as was the blocks main effect, F (9, 216) = 10.30, $p < .001$. Post hoc analysis (using the Scheffé correction procedure) of the 3-way interaction indicated patterning in the single-alternation groups (R trials faster than N trials) on Blocks [...] and 9, ps < .05. The *Ss* in the double-alternation groups did not differ in speed on N and R trials except on Block [...] (R trials faster than N trials, $p < .0$[...] Thus, in the present experiment the [...]

dence for patterning must be considered marginal, since faster running on R trials for the single-alternation groups was observed on only 2 trial blocks. There seem to be 3 possible explanations for the failure to find reliable patterning behavior: (*a*) It is possible that an insufficient number of acquisition training trials were run, since the patterning that was observed occurred late in acquisition. (*b*) The ITI during acquisition may have been too long (5–6 min.) for patterning to occur. In the appetitive situation, some investigators have observed patterning at long ITIs (e.g., Capaldi & Lynch, 1966), but others have failed to do so (e.g., Surridge & Amsel, 1966). Although a 5–6-min. ITI cannot be considered extremely long, it is nonetheless, substantially longer than the 15–30-sec. ITIs that are often used in sequential experiments. (*c*) Acquisition training may have consisted of too few trials in each daily session (4 per day) for patterning to develop. Bloom and Capaldi (1961), for example, demonstrated patterning by single-, but not double-alternation *S*s; they used a procedure that employed 12 trials per day, considerably more than in the present experiment. Thus, it is possible that any of these factors, or a combination of them, were responsible for the lack of patterning in the present data; or that patterning is difficult to obtain in escape conditioning.

Extinction. The start-speed data from extinction were blocked in 4-trial blocks (days) and analyzed via a 5 × 10 (Group × Days) analysis of variance. The extinction data may be seen in Figure 4. The analysis revealed significant main effects for groups, F (4, 30) = 60.58, $p < .001$, and days, F (9, 270) = 52.24, $p < .001$, as well as a significant Groups × Days interaction, F (36, 270) = 15.02, $p < .001$. Post hoc analysis (using the Scheffé procedure) indicated that all PRF groups were more resistant to extinction than Group CRF on all days (all ps $< .01$). There was no difference in the 2 single-alternation groups (NRNR and RNRN) throughout extinction. Group NNRR was more resistant to extinction than all other

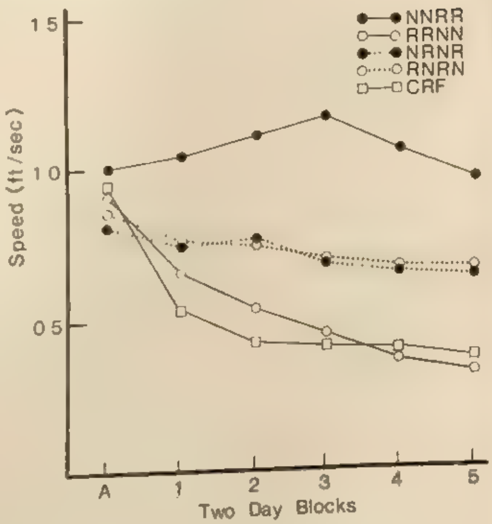

FIGURE 4. Mean start speeds for the last day of acquisition (A) and 10 days of extinction (in 2-day blocks).

groups for all days of extinction (all ps $< .01$). The RRNN group was inferior to Groups NRNR and RNRN on all days of extinction (all ps $< .01$) except Day 3, where no differences in the 3 groups were observed. Groups RRNN and CRF did not differ in Rn except on Days 1 and 3, where RRNN was faster than CRF ($p < .01$ in both cases).

The extinction results of the present experiment are consistent with those of Experiment II, i.e., following extended acquisition, a long-N-length group (Group NNRR) was more resistant to extinction than a short-N-length group (Groups NRNR and RNRN). The present experiment also graphically illustrates the importance of another sequential variable, N–R transitions, in determining response persistence. Group RRNN received an N length of 2 in the present experiment, but received no N–R transition in its daily trial schedule (compared with Group NNRR, which received an N length of 2 plus an N–R transition on each day of acquisition) and showed only slightly more Rn than Group CRF. This comparison demonstrates that in order for N length to be a factor in increased Rn, it must be followed by at least 1 R trial. This finding

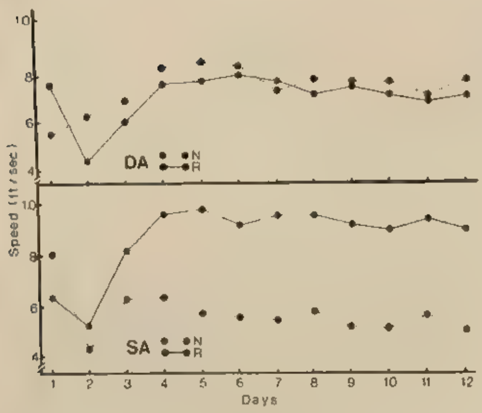

FIGURE 5. Mean start speeds on reinforced (R) and nonreinforced (N) trials for 12 days of acquisition.

is similar to results from appetitive experiments using similar reward schedules (Spivey & Hess, 1968; Spivey, Hess, & Black, 1968).

EXPERIMENT V

This experiment was designed to further investigate patterning behavior in instrumental escape conditioning. In an attempt to provide more favorable conditions for patterning to occur, a number of changes were made in the procedure. Specifically, more trials were run per day for each *S* (8 instead of 4), and the ITI was shortened considerably (45 sec. rather than 5–6 min.).

Method

Subjects. The *S*s were 24 male albino rats of the Sprague-Dawley strain, purchased from the Holtzman Co. They were approximately 125 days old at the start of the experiment and were randomly assigned to 1 of 3 groups (n = 8/group).

Procedure. Throughout the experiment, *S*s were housed individually and maintained on an ad-lib schedule of food and water. One day prior to the start of the experiment, all *S*s were given 2 reinforced pretraining trials in the apparatus. Reinforced and nonreinforced trials were conducted exactly as in Experiment III.

Acquisition training consisted of 8 trials per day for 12 days, a total of 96 acquisition trials. Two groups received a 50% PRF schedule during acquisition, while a third group (Group CRF) was reinforced on all trials during acquisition. The PRF groups differed only in the schedule of N and R trials received during acquisition. The single-alternation (SA) group received an NRNRNR R trial schedule on all 12 days of acquisition, while the double alternation (DA) group received an NNRRNNRR trial schedule on all 12 days. The *S*s were run in squads of 6 (2 *S*s from each group in each squad) with an ITI of 45 sec. for each *S*.

Following acquisition training, all *S*s were given 8 extinction trials per day for 5 days, a total of 40 extinction trials. The procedure on extinction trials was exactly the same as that for N trials during acquisition.

Results and Discussion

Acquisition. An analysis of variance performed on the mean of all 8 trials for the last day of acquisition indicated no terminal acquisition differences, F (2, 21) < 1. In order to examine possible patterning behavior the start-speed data from the 2 PRF groups were combined into 8-trial blocks (days) and analyzed by a 2 × 2 × 12 (Type of Trial—N or R × N Length × Days) analysis of variance. The main effect of type of trial was not significant, F (1, 14) < 1, although the Type of Trial × N Length interaction, F (1, 14) = 81.00, p < .001, and the of Trial × N Length × Days interaction, F (11, 154) = 6.71, p < .001, were significant. The N length main effect was significant, F (1, 14) = 37.12, p < .001, as was the days main effect, F (11, 154) = 3.82, p < .001. The N Length × Days interaction was significant, F (11, 154) = 2.43, p < .01, while the Type of Trial × Days interaction failed to reach an acceptable level of significance, F (11, 154) < 1. Post hoc analysis (using the Scheffé procedure) indicated that patterning began to appear on Day 3 (R trials faster than N trials, p < .05) and was reliable thereafter (Days 4–12, ps < .01) for Group SA. The only differences observed in Group DA were on Day 1 (R trials faster than N trials, p < .01) and Day 2 (N trials faster than R trials, p < .01); thereafter, there were no statistically reliable differences in speeds on N and R trials for Group DA. The acquisition data from Experiment V may be seen in Figure 5.

Thus, the present results demonstrate that reliable patterning behavior can occur in instrumental escape conditioning, although it seems to appear much earlier in

training than in similar appetitive procedures, and that massing of trials and/or fairly short ITIs are sufficient conditions for its occurrence.

Extinction. A 3 × 5 (Groups × Days) analysis of variance performed on start speeds revealed a significant groups main effect, F (2, 21) = 58.94, $p < .001$, and a significant days main effect, F (4, 84) = 2.71, $p < .05$, while the Groups × Days interaction failed to reach an acceptable level of significance, F (8, 84) < 1. Post hoc analysis (again using the Scheffé correction procedure) indicated that the groups were ordered in terms of Rn as follows: DA > SA > CRF (all ps < .01). The extinction data for Experiment V may be seen in Figure 6. The extinction results of the present experiment are consistent with those of Experiments II and IV in demonstrating that, following extended acquisition training, *S*s receiving longer N lengths are more resistant to extinction than *S*s receiving shorter N lengths. Even though *S*s in Group SA patterned, they were more resistant to extinction than Group CRF; this result is similar to extinction data in a number of appetitive patterning studies (e.g., Rudy, 1971).

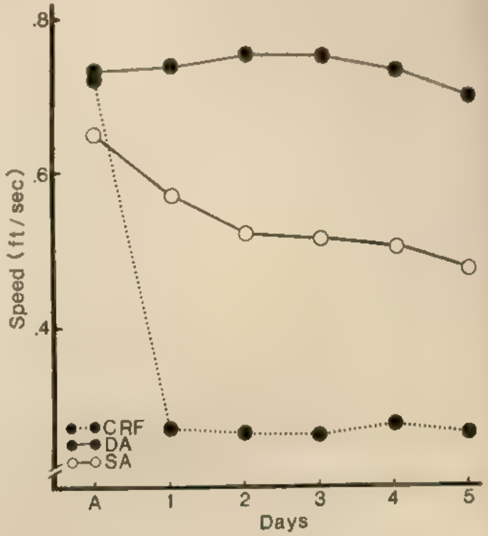

FIGURE 6. Mean start speeds for the last day of acquisition (A) and 5 days of extinction.

GENERAL DISCUSSION

Two general conclusions may be drawn from the data presented herein: (*a*) A reliable partial reinforcement extinction effect (PRE) was observed in all 4 experiments where a CRF control group was employed (Experiments I, II, IV, and V). The PRE is, of course, also reliably observed in appetitive instrumental conditioning, and has been previously demonstrated in escape conditioning (e.g., Bower, 1960; Woods et al., 1972). (*b*) In all 4 experiments where a CRF control group was used (Experiments I, II, IV, and V), there were no differences between the PRF and CRF groups at the end of acquisition. This result is in disagreement with some studies (e.g., Bower, 1960; Woods et al., 1972, with large magnitude of reinforcement) which have shown superiority for a CRF group at the end of acquisition. The reasons for this discrepancy are not clear at the present time. The present data are also discrepant in this respect with much of the appetitive conditioning literature in that PRF *S*s are often superior to CRF *S*s at the end of acquisition.

Several statements can also be made in relation to the effects of specific sequential variables in instrumental escape conditioning.

1. All 5 of the present experiments demonstrate N length effects very similar to those found in sequential appetitive conditioning studies. After limited acquisition, *S*s receiving short N lengths show more Rn than *S*s receiving long N lengths (Experiments I and III); and the opposite is true following extended acquisition (Experiments II, IV, and V). Thus the Schedule of Reward × Number of Acquisition Trials interaction seems to be a reliable finding in instrumental escape conditioning.

2. The occurrence of N–R transitions was shown to be important in escape conditioning, much as it has been in appetitive procedures. The effects of N–R transitions were most pronounced in Experiment IV where 1 double-alternation group (Group NNRR), which received 1 N–R transition per day, demontrated the greatest resistance to extinction, while the second double-alternation group (RRNN), which received no N–R transitions, was only slightly more resistant to extinction than the CRF control group. The slight superiority of Group RRNN over Group CRF can be accounted for by the fact that on each day of acquisition *S*s in Group RRNN

received an N–R transition with an ITI of 24 hr. Mellgren and Seybert (1973) have shown that N–R transitions with a long ITI in acquisition can increase massed-trials extinction performance. According to sequential theory, the number of N–R transitions is also postulated as the theoretical determinant of Rn after limited acquisition in appetitive situations (the number of N–R transitions determines the habit strength of the S^N–R_I association that determines Rn) and since the empirical data resulting from appetitive procedures and the present escape experiments are so similar, there is no reason to assume any different mechanism in escape conditioning. Thus, the results of Experiments I and III also implicate the importance of N–R transitions in determining Rn in escape conditioning. A more complete theoretical account of the sequential mechanisms that determine Rn after both limited and extended acquisition may be found elsewhere (e.g., Capaldi, 1967).

3. Pattern of N and R trials was shown to be an important variable in escape conditioning in Experiment V, where *S*s which received a regular single alternation schedule (Group SA) learned to run fast on R trials and slowly on N trials. These data are similar to those obtained when single-alternation schedules are used in appetitive in- [illegible] ing occurred earlier in escape training (after approximately 30 trials) than is usual with appetitive procedures.

Thus, the results of the present experiments demonstrate the operation of a number of [illegible] conditioning. These sequential variables were found to operate in escape conditioning in much the same way as they do in corre- [illegible]ng appetitive procedures. Therefore, the results may be seen as support for the hypothesis that Capaldi's (1967) sequential [illegible] mental escape conditioning phenomena. The present experiments join several others (e.g., Campbell et al., 1973; Capaldi & Levy, 1972; Dyck et al., 1974) in demonstrating that the boundary conditions of sequential theory may be expanded to include a number of aversive conditioning situations.

It should be noted, however, that some differences do exist between the present data [illegible] experiments. In appetitive experiments, the effects of sequential manipulations are usually observed in all runway sections (i.e., start, run, and goal). In the present escape conditioning experiments, the differences between groups as a result of the manipulation of sequential variables occurred most reliably in the start section. Although in some of the experiments differences did occur in other runway sections (e.g., the goal section in Experiment I, the run section in Experiment II, and the run and goal sections in Experiment III), these effects were most apparent in the start-speed measure. In Experiments IV and V, however, differences were observed in *only* the start section. Capaldi and Levy (1972), using punishment superimposed on a partial food reward schedule, also observed sequential effects predominantly in the start section of a straight runway. They attributed their results to a heightened avoidance gradient resulting from the highly aversive goal situation. The present data may be due to similar factors, although the punishment and escape procedures are somewhat different, particularly in relation to the locus and duration of the shock received by *S*. A second possible explanation for the present find[illegible] may lie in the number of acquisition tra[illegible] trials (120 in Experiment IV and 96 in [illegible]periment V). After large numbers of trials, the running response, as it occurs in the presence of shock, may become rather insensitive to other variables. Therefore, after relatively extended acquisition training, the main effect of acquisition variables may be restricted to the likelihood of the initiation of the running response, rather than speed of running after the response is initiated. This difference may be of considerable theoretical [illegible] and should be investigated [illegible]

ROTARY ACCELERATION OF A SUBJECT IN[illegible] E REACTION TIME TO MOTION IN PERIPH[illegible]

JAMES M. BORKENHAGEN[1]

California State University, San Jose

The effect of *S*'s rotary acceleration upon choice reaction ti[illegible] accelerating target in peripheral vision was the central issue in [illegible] with the level of acceleration and the viewing angle of the [illegible] variables. Twelve pilots were tested in a rotation device unde[illegible] visual stimulation alone and visual-plus-rotary stimulation. [illegible] sponded to the direction of the visual motion by moving a han[illegible] the right or left. Visual-plus-rotary stimulation produced lon[illegible] than the visual stimulation alone. Choice RT was inversely [illegible] level of acceleration and directly proportional to the viewing [illegible] findings are discussed in connection with theories of double stimula[illegible] intersensory effects.

A number of experiments have demonstrated that reaction time (RT) to a signal can be modified by the presentation of a secondary stimulus in conjunction with the primary signal. Some investigators have found a longer RT to double stimulation, even though the secondary stimulus required no response from the *S* (Koster & Bekker, 1967; Nickerson, 1967). Presentation of stimuli to 2 sensory modalities has, however, produced contrasting results, since intersensory experiments commonly show a facilitation of RT by the accessory stimulus (Bernstein, 1970; Swink, 1966; Symons, 1963). It is clear that either facilitation or inhibition of RT may result from double stimulation, depending upon a number of experimental variables.

The inhibition of RT by accessory stimulation has often been interpreted as evidence for single-channel processing of perceptual information. Theoretical approaches such as those reviewed by Broadbent (1958) emphasize the limited capacity of the central nervous system (CNS) to handle information [illegible]nd, facilitation of RT by a s[illegible]lus has generated anot[illegible]es. Among these are theori[illegible]ming (Symons, 1963) and energy int[illegible]gration (Bernstein, 1970). Explanations of both facilitation and i[illegible] of RT focus upon the informati[illegible] istics of the CNS.

The present study used [illegible] of a visual and a [illegible] stimulus, which were presented to *S* simultaneously. An accelerating visual target served as the visual stimulus, and the vestibular stimulus was a rotary acceleration. A directional response was required to the visual motion only, so the rotary acceleration represented an accessory stimulus. This experiment can therefore be characterized as intersensory, with the 2 stimuli being presented simultaneously and the response required to the visual motion only. The specific purpose of this study was to investigate the effects of 5 levels of rotary acceleration of the *S* on choice RT to the acceleration of a lumin[illegible] line in central and peripheral vision.

Method

Subjects. Twelve commercial airline pilots were paid for their participation in the experiment. All showed normal response to angular acceleration in previous testing.

Apparatus. The Man-Carrying Rotation Device (MCRD) produced the rotary accelerations in the experiment. The MCRD is a 1-degree-of-freedom

[1] This research was conducted at Ames Research Center, Moffett Field, California, under National Aeronautics and Space Administration Grant NGL-05-046-002 to California State University, San Jose. The author thanks Brant Clark, principal investigator, and John Stewart, technical monitor, for their support in this experiment.

simulator which rotates the *S* about an earth-vertical axis, providing angular accelerations that have a rise time of about 100 msec. and may be regulated from .01° to 30°/sec². The MCRD has been described in detail by Clark and Stewart (1968). The *S* sat in an aircraft seat at the center of rotation of the MCRD cab. He wore an aviator's helmet, lap belt, and shoulder harness throughout all testing, and he communicated with *E* through a voice communication system. A helmet headrest was provided to hold *S*'s head stationary.

A perimeter arc extended across the horizontal meridian of *S*'s right temporal field of vision. The arc was made of plastic and had a radius of 66 cm. Fixation points consisting of white numerals on a black background were located on the arc at 10° intervals up to 60° from the axis of direct vision. Each numeral (6 × 8 mm.) corresponded to the angular distance from direct viewing, e.g., 0–0°, 1–10°, 2–20°.

The visual stimulus was a movable vertical line (18 cm. long) centered on the screen of a cathode ray tube (CRT). The CRT was located 66 cm. in front of *S*, and its screen measured 36 × 28 cm. The line could be accelerated on the screen to the right or left with a rise time equivalent to that of the rotary acceleration. The *S* responded to the acceleration of the line by deflecting a vertical response stick (8 cm. long) located on the right armrest of the aircraft seat. A force of 110 gm. to the right or 140 gm. to the left was necessary to register a response. The choice RT was registered in milliseconds on a digital voltmeter as the time from the onset of acceleration to the moment *S* responded. An ink-writing recorder collected a record of the accelerations of the line and the MCRD, and the signal from the response stick could also be monitored on this device.

Procedure. The *S* was instructed to respond to the movement of the line by deflecting the response stick in the same direction as the line motion, and he was asked to react as quickly as possible without making an error. When an error was made, the trial was repeated at the end of the series. The *S* sat in the illuminated MCRD cab and viewed the line on the CRT screen. By fixating on the appropriate numeral on the perimeter arc, he observed the line at various points in the left periphery. Binocular vision was used throughout the experiment, but 5 *S*s could not see the line binocularly at 60° because the nasal ridge obscured the vision of the right eye.

There were 2 primary experimental conditions: (*a*) choice reaction to the movement of the line alone, and (*b*) choice reaction to the line motion with simultaneous rotary motion. The rotary acceleration, when present, was in the direction opposite from the acceleration of the line. The 2 accelerations were, however, of equal magnitudes. All *S*s received both stimulation conditions, half of them receiving Condition *a* first and half receiving Condition *b* first. Five levels of acceleration were given in each condition: 1°, 2°, 3°, 6°, and 12°/sec². These levels of angular acceleration are well above the thresholds determined for these pilots by psychophysical methods. Each level of acceleration was tested at the following 7 points in the visual field: 0°, 10°, 20°, 30°, 40°, 50°, and 60° to the left of fixation. The order of presentation of the levels of acceleration and the peripheral angles was randomly determined, as was the direction of acceleration on each trial.

At the start of each trial, the line was centered on the CRT screen. The number of the fixation point for the trial was announced over the voice communication system, and *S* acknowledged the number. Following a standby–ready exchange, the acceleration was applied. The foreperiod from *S*'s reply to the moment of acceleration varied between 1 and 3 sec., so it was not possible for him to anticipate the acceleration with much accuracy. The *S* terminated both the acceleration of the line and the MCRD when he responded, and a minimum of 20 sec. elapsed before the next acceleration.

Three experimental trials were given at each of the 70 combinations of stimulation condition (2), level of acceleration (5), and position in the visual field (7). The testing was organized in blocks, all the trials within a block being at one level of acceleration. Practice trials preceded the experimental trials at all levels of acceleration. Fourteen practice trials were given before the first block of experimental trials in both stimulation conditions: The first 7 trials included all levels of acceleration, whereas the second 7 trials included only the level of acceleration of the experimental trials that followed. The blocks of experimental trials following the first block in each condition were preceded by only 7 practice trials, all of them at the level of acceleration of the subsequent experimental trials. During a testing session, *S* completed 1 or 2 blocks of experimental trials together with the appropriate practice trials. He completed 3 testing sessions in a day: 2 sessions of 2 blocks each and 1 session of 1 block. Two mornings of testing were required of each *S* to complete the experiment.

Results

Choice RT was the dependent variable used in the data analysis. The mean of the 3 experimental choice RTs at each of the 70 treatment combinations was calculated for each *S*, and an analysis of variance was carried out to determine the effects of stimulation condition, level of acceleration, and peripheral angle on choice RT. The analysis followed a 2 × 5 × 7 repeated measures design, with the *S*s factor treated as a random variable. Errors in responding to the direction of the visual acceleration were infrequent, the overall error rate being 1.6%. There were, however, marked differences between *S*s in the number of errors committed.
